Reaction of  $\text{TiCl}_4$  and  $\text{B}_2[\text{NMe}_2]_4$  gives the unusual  $\{[\text{Me}_2\text{N}]_2\text{BCl}\}_2[\text{TiCl}_4]_3$  species, as well as small quantities of  $\text{Me}_2\text{NTiCl}_3$  and  $\text{Me}_2\text{NBu-Ti}_2\text{Cl}_6$ .<sup>20</sup> The latter complex contains coordinated dimethylamino moieties, and a pentacoordinate structure has been proposed.<sup>21</sup> The  $\text{Ti}_5\text{Cl}_{11}^-$  ion has been isolated in the salt  $[(\text{Ph}_3\text{P})_3\text{PtCl}]^+ [\text{Ti}_5\text{Cl}_{11}]^-$ .<sup>22</sup>

Concomitant with the work on the chloride system,  $\{[\text{Me}_2\text{N}]_2\text{BBR}_2\}_2[\text{TiBr}_4]_3$  has been prepared, and the following coordination has been proposed:<sup>23</sup>

Scheme 2

Reaction of  $\text{TiBr}_4$  with  $\text{B}_2[\text{NMe}_2]_4$  gives dinuclear  $\text{B}_2\text{Br}_2[\text{NMe}_2]_2\cdot\text{TiBr}_3$  (**1**).<sup>24</sup> Complexes  $\text{M}_2[\text{TiBr}_5(\text{H}_2\text{O})]$  ( $\text{M} = \text{Cs}, \text{Rb}, \text{pyH}$ ) are also known.<sup>25</sup>

The species  $\text{TiI}_6^{2-}$  is unknown. The only evidence for its formation comes from the treatment of  $[\text{Et}_4\text{N}]_2\text{TiCl}_6$  with liquid HI, which yields a very unstable black solid. It has been predicted, by comparison with the electronic spectra of the  $\text{TiX}_6^{2+}$  ( $\text{X} = \text{Cl}, \text{Br}$ ) species, that  $\text{TiI}_6^{2-}$  would be black.<sup>26</sup>

## 4 COORDINATION CHEMISTRY

A large number of titanium complexes are known and it is not possible to review the literature comprehensively in the space available. More comprehensive treatises have been published by Stephan,<sup>27</sup> McAuliffe,<sup>26</sup> and Clark.<sup>14</sup> Titanium in its common oxidation states is quite labile. Water exchange is used as a convenient benchmark. The rate constant for water exchange in the  $\text{Ti}^{\text{III}}$  species  $[\text{Ti}(\text{H}_2\text{O})_6]^{3+}$  is  $1.8 \times 10^5 \text{ s}^{-1}$  at room temperature,<sup>28</sup> and a lower limit of  $3.4 \times 10^3 \text{ s}^{-1}$  has been placed on the exchange of terminal water ligands in oligomeric hydrolyzed  $\text{Ti}^{\text{IV}}$  solutions.<sup>29</sup> These values can be compared to rate constants for exchange of  $1.6 \times 10^2 \text{ s}^{-1}$  for  $[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$  and  $2.4 \times 10^{-6}$  for the famously inert  $[\text{Cr}(\text{H}_2\text{O})_6]^{3+}$ .<sup>30</sup>

### 4.1 Low-valent Titanium Complexes

Although the coordination chemistry of  $\text{Ti}^{\text{IV}}$  and, to a lesser extent,  $\text{Ti}^{\text{III}}$  has been relatively well investigated, few complexes are known in the lower oxidation states and are almost all unstable to oxidation.<sup>10,14,26,27</sup> Reduction of  $\text{TiCl}_4$  with excess of dilithium 2,2'-bipyridyl in THF with excess bipyridyl gives  $\text{Li}[\text{Ti}(\text{bpy})_3]\cdot 3\text{THF}$ , as shown in equations (5) and (6). Further reduction to  $\text{Li}_2[\text{Ti}(\text{bpy})_3]\cdot 3.7\text{THF}$  is possible.<sup>26</sup>

Diazadiene or diimine ligands of the general type  $\text{R}-\text{N}=\text{CH}-\text{CH}=\text{N}-\text{R}$  (Rdab) are known to stabilize complexes in low oxidation states.<sup>31</sup> Cloke and coworkers have

prepared titanium(0) complexes of Rdab ( $\text{R} = i\text{-Pr}, i\text{-Bu}$ ) by cocondensation of titanium vapor with an excess of ligand in heptane.<sup>32</sup>  $[\text{Ti}(\sigma, \sigma\text{-}N, N'\text{-}i\text{-Prdab})_3]$  (**2**) is an air-sensitive, blue colored crystalline solid.  $^1\text{H}$  NMR data show the methyl groups of  $i\text{-Pr}$  substituents to be diastereotopic, confirming that the titanium center has octahedral coordination.  $[\text{Ti}(\sigma, \sigma\text{-}N, N'\text{-}t\text{-Budab})_2]$  (**3**) forms as air-sensitive, red colored crystals. The latter complex is four-coordinate, and is presumed to be tetrahedral. Photoelectron spectroscopic data for both complexes confirm that coordination occurs through the N atoms of the ligands.

Titanium(II) complexes are better understood. Reaction of the deeply colored  $\text{TiX}_2(\text{MeCN})_2$  ( $\text{X} = \text{Cl}, \text{Br}$ ) complexes with other ligands gives  $\text{TiCl}_2\text{L}_2$  ( $\text{L} = \text{C}_4\text{H}_8\text{O}, \text{C}_5\text{H}_{10}\text{O}, \text{py}, 0.5\text{bpy}, 0.5\text{phen}$ ) and  $\text{TiBr}_2(\text{bpy})$ . The latter species react with water to liberate dihydrogen.<sup>33</sup> One example of an aquo-coordinated  $\text{Ti}^{\text{II}}$  complex was recently described, however. The UV/visible spectrum and structure from X-ray powder data of the aqueous  $\text{Ti}^{\text{II}}$  compound,  $\text{TiF}_2(\text{H}_2\text{O})_4$ , were recorded after its formation from the dissolution of titanium metal in strong acid.<sup>34</sup>

Reaction of  $\text{Na}_2\text{TiCl}_4$  with  $\text{NMe}_3$  results in oxidation of the halide, leading to the formation of  $\text{TiCl}_3(\text{NMe}_3)_2$ .<sup>35</sup> Dialkylamides of  $\text{Ti}^{\text{II}}$  can be prepared by the volatility-controlled disproportionation of  $\text{Ti}^{\text{III}}$ .<sup>36</sup>

Gambarotta and coworkers have shown that reduction of  $\text{TiCl}_3(\text{THF})_3$  with lithium, in the presence of a large excess of TMEDA, allows the large-scale preparation of  $\text{trans}-(\text{TMEDA})_2\text{TiCl}_2$ .<sup>37</sup> The TMEDA ligands are easily replaced by other amines, allowing the quantitative preparation of  $\text{TiCl}_2\text{L}_4$  ( $\text{L} = 0.5N, N', N'\text{-trimethylethylenediamine}, \text{py}, 0.5\text{bpy}$ ).<sup>37</sup> Furthermore, reaction of  $\text{trans}-(\text{TMEDA})_2\text{TiCl}_2$  with  $(\text{Me}_3\text{Si})_2\text{NLi}$  leads to the formation of  $\{[(\text{Me}_3\text{Si})_2\text{N}]\text{TiCl}(\text{TMEDA})\}_2[\mu\text{-N}_2]$  (**4**).<sup>38</sup> The complex consists of two identical  $\{[(\text{Me}_3\text{Si})_2\text{N}]\text{TiCl}(\text{TMEDA})\}$  fragments, each bonded to one of the two nitrogen atoms of a bridging dinitrogen moiety. The  $\text{Ti}-(\mu\text{-N}_2)-\text{Ti}$  moiety is almost linear. The  $\text{Ti}-\text{N}$  bonds are short,  $1.762 \text{ \AA}$ , while the  $\text{N}-\text{N}$  distance is long,  $1.289 \text{ \AA}$ , indicating considerable electronic delocalization over the  $\text{Ti}_2(\mu\text{-N}_2)$  moiety. The titanium atom has a square pyramidal coordination geometry, but is elevated  $0.466(3) \text{ \AA}$  above the plane. However, reaction with 2 equiv of  $(\text{Me}_3\text{Si})_2\text{NLi}$  in the presence of TMEDA yields the black crystalline solid

$\{[(\text{Me}_3\text{Si})_2\text{N}]_2\text{Ti}\}_2(\mu\text{-}\eta^2\text{-}\eta^2\text{-}\text{N}_2)_2[(\text{TMEDA})_2\text{Li}]$  (**5**), which is a mixed-valence  $\text{Ti}^{\text{I}}/\text{Ti}^{\text{II}}$  species.<sup>38</sup> The X-ray crystal structure of (**5**) shows it to consist of two separate  $[\text{Li}(\text{TMEDA})_2]$  and  $\{[(\text{Me}_3\text{Si})_2\text{N}]_2\text{Ti}\}_2(\mu\text{-}\eta^2\text{-}\eta^2\text{-}\text{N}_2)_2$  ionic fragments. The titanium-containing unit is dinuclear and is formed by two  $[(\text{Me}_3\text{Si})_2\text{N}]_2\text{Ti}$  groups that are symmetrically and perpendicularly arranged on the two sides of the two parallel dinitrogen molecules. Both titanium atoms are six coordinate, four of the coordination sites being occupied by the four nitrogen atoms of the two coplanar dinitrogen molecules. The N–N distance (1.379 Å) is significantly longer than that displayed in complex (**4**). The Ti–N distances are similarly elongated (Ti(1)–N(3) = 2.236 Å, Ti(1)–N(4) = 2.290 Å). These differences in the bond lengths are attributed to the different modes of bonding in the two complexes. The different bonding mode of the dinitrogen moiety in the two complexes (i.e. end-on versus side-on) could only be attributed to the different steric bulk of the two complexes.

The cyclopentadienyl derivative of titanium(II),  $\text{Cp}_2\text{Ti}$  (see **Titanium: Organometallic Chemistry**), has eluded isolation as a discrete compound.<sup>26</sup> However,  $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2$  (equation 7) provides a convenient route to the  $\text{Cp}_2\text{Ti}$  unit since the two phosphine ligands are easily displaced by a large number of substrates (e.g. CO,  $\text{C}_4\text{H}_4$ ,  $\text{C}_4\text{H}_8$ , dmpe, MeCN) under very mild conditions.<sup>39</sup>

Phosphine complexes of the second and third row transition elements are common; in contrast, those of the early first-row transition elements are not.<sup>40</sup> Wilkinson and coworkers prepared a series of *trans*- $\text{MCl}_2(\text{dmpe})_2$  complexes ( $\text{M} = \text{Ti}, \text{V}, \text{Cr}, \text{Mn}, \text{Fe}$ ).<sup>41</sup> The red–black colored titanium complex *trans*- $\text{TiCl}_2(\text{dmpe})_2$  was prepared in high yield by reacting  $\text{TiCl}_4$ , dmpe, and magnesium in THF. The complex was characterized using X-ray crystallography, which confirmed the *trans* geometry of the ligands. Attempts to prepare  $\text{TiMe}_2(\text{dmpe})_2$  by alkylating  $\text{TiCl}_2(\text{dmpe})_2$  with MeLi or  $\text{Me}_2\text{Mg}$  were unsuccessful, leading only to the isolation of a red–black material of stoichiometry *trans*- $\text{TiMe}_{1.3}\text{Cl}_{0.7}(\text{dmpe})_2$ , which was considered to be a mixture

of  $\text{TiMeCl}(\text{dmpe})_2$  and  $\text{TiMe}_2(\text{dmpe})_2$ . The reaction of  $\text{TiCl}_3 \cdot \text{THF}$  or  $\text{TiCl}_4 \cdot 2\text{THF}$  with  $\text{LiPCy}_2$  yields the dark brown adduct  $\text{Ti}(\text{PCy}_2)_2$ .<sup>42</sup> This complex is pyrophoric and reacts readily with iodine in benzene to give  $\text{TiI}_2(\text{PCy}_2)_2$  and  $\text{TiI}_3(\text{PCy}_2)_2$ .<sup>42</sup>

## 4.2 Titanium(III) Complexes

The magnetic and electronic properties of  $\text{Ti}^{\text{III}}$  complexes have been well studied. Nearly all  $\text{Ti}^{\text{III}}$  complexes exhibit room temperature–magnetic moments close to the spin-only value of 1.73 BM.<sup>10,14,26</sup> However, rather than showing a great deal of temperature dependence, as would be expected for a  $d^1$  ion in an electrostatic field of perfect  $O_h$  symmetry, the magnetic moments level off and in general vary from ~1.5 BM at 80 K to ~1.8 BM at about 300 K. These effects arise because of distortion and covalence, which cause a delocalization of the electron<sup>10,14,26</sup> (see **Magnetism of Transition Metal Ions**).

The electronic spectra of  $\text{Ti}^{\text{III}}$  complexes can give a hint to quite subtle structural information. In a perfect octahedral field, the  ${}^2\text{D}$  ground term of  $\text{Ti}^{\text{III}}$  is split into a  ${}^2\text{T}_{2g}$  lower term and a  ${}^2\text{E}_g$  upper term. The broad asymmetric band at ca.  $20\,100\text{ cm}^{-1}$  in the visible spectrum of  $\text{Ti}(\text{H}_2\text{O})_6^{3+}$  arises from a  ${}^2\text{T}_{2g} \rightarrow {}^2\text{E}_g$  transition. The energy of this transition for a complex is a direct measure of the ligand field strength. The asymmetry comes from splitting of the  ${}^2\text{E}_g$  term as a consequence of the Jahn–Teller effect.<sup>26</sup>

Most  $\text{Ti}^{\text{III}}$  complexes are octahedral and are produced by reacting  $\text{TiCl}_3$  with an excess of ligands, giving rise to a range of stoichiometries, for example,  $[\text{TiL}_6]^{3+}$ ,  $[\text{TiL}_4\text{X}_3]$ ,  $[\text{TiL}_3\text{X}_3]$ , and  $[\text{TiL}_2\text{X}_4]^-$ . Fowles and coworkers isolated a range of  $\text{Ti}^{\text{III}}$  iodide complexes,  $\text{TiI}_3\text{L}_2$ ,  $\text{TiI}_3\text{L}_3$  ( $\text{L} = \text{NMe}_2$ , py,  $\alpha$ -picoline), and  $\text{TiI}_3(\text{MeCN})_4$ , the last being assigned the formula  $[\text{TiI}_2(\text{MeCN})_4]\text{I}$ .<sup>43</sup> The X-ray crystal structure of  $\text{TiBr}_3(\text{NMe}_3)_2$  shows it to be monomeric with a trigonal bipyramidal structure.<sup>44</sup> In contrast, reaction of  $\text{TiCl}_3[\text{N}(\text{SiMe}_3)_2]_3$  with  $\text{LiN}(\text{SiMe}_3)_2$  yields  $\text{Ti}[\text{N}(\text{SiMe}_3)_2]_3$ , which is a rare example of a three-coordinate  $\text{Ti}^{\text{III}}$  complex.<sup>45</sup>

Bi- and polydentate ligands also form  $\text{Ti}^{\text{III}}$  complexes with a variety of stoichiometries. For example,  $[\text{Ti}(\text{L})_3]^{3+}$  complexes are produced by the ligands en and pn,<sup>14</sup> whereas bpy and phen give  $[\text{TiCl}_2(\text{L})_2][\text{TiCl}_4(\text{L})]$ ,<sup>14</sup>  $[\text{TiL}_2(\text{phen})_2]\text{I}$ ,<sup>43</sup> and  $[\text{TiL}_2(\text{bpy})_2][\text{TiL}_4(\text{bpy})]$ .<sup>43</sup>

A number of neutral and anionic complexes containing oxalato ligands have been prepared, for example,  $\text{Ti}_2(\text{ox})_3 \cdot 10\text{H}_2\text{O}$ ,<sup>46</sup>  $\text{Cs}[\text{Ti}(\text{ox})_2(\text{H}_2\text{O})_3] \cdot 2\text{H}_2\text{O}$ ,<sup>47</sup> and  $\text{K}_3[\text{Ti}(\text{ox})_3(\text{H}_2\text{O})] \cdot 6\text{H}_2\text{O}$ .<sup>48</sup> All contain seven-coordinate pentagonal bipyramidal Ti atoms, though an eight-coordination sphere has been proposed for the  $\text{K}[\text{Ti}(\text{ox})_2] \cdot 2\text{H}_2\text{O}$  complex.<sup>26</sup>

Bowden and Ferguson obtained an interesting range of  $\text{Ti}^{\text{III}}$  Schiff-base complexes starting from  $\text{TiCl}_3(\text{THF})_3$  and potentially quadridentate Schiff bases.<sup>49</sup> Species (**6**), initially green, slowly turns red (**7**) on stirring in THF. Reduction of  $[\text{TiCl}_2(\text{salen})]$  with zinc dust in THF gives  $[\{\text{Ti}(\text{salen})(\text{THF})_2\}][\text{ZnCl}_4]$ . Magnetic moments ( $\mu_{\text{eff}} =$

0.96 BM) suggest a strong Ti–Ti interaction. Treatment of the blue solution with pyridine leads to the isolation of monomeric  $[\text{TiCl}(\text{salen})(\text{py})]\cdot\text{THF}$ .<sup>49</sup> Reaction of  $\text{TiCl}_3$  with the macrocyclic ligand 1,4,7-trimethyl-1,4,7-triazacyclononane (tacn) at 20 °C affords blue  $[(\text{tacn})\text{TiCl}_3]$ , while at higher temperatures, this reaction leads to the formation of green colored crystals containing  $[(\text{tacn})\text{Ti}^{\text{III}}\text{Cl}_3]$ , with  $[(\text{tacn})\text{Ti}^{\text{IV}}(\text{O})\text{Cl}_2]$  as an impurity.<sup>50</sup>

Titanium(III) phosphine complexes have received more attention than their titanium(II) analogs.<sup>40</sup> The first titanium(III) phosphine complex,  $\text{TiCl}_3(\text{PEt}_3)\cdot\text{C}_2\text{H}_4$ , was prepared by Chatt *et al.*<sup>51</sup> More recently, the monomeric complexes  $\text{TiCl}_3(\text{PR}_3)_2$  ( $\text{R} = \text{MeH}_2, \text{Me}_2\text{H}, \text{Me}_3, \text{Et}_3$ ) have been prepared by the direct reaction of the components in toluene at 85 °C.<sup>52</sup> Weaker donors such as  $\text{PPh}_3$  and  $\text{PCl}_3$  do not complex with titanium(III). Recent work has also shown that  $\text{TiCl}_3(\text{THF})_3$  reacts with the diphosphine *i*-Pr<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>P-*i*-Pr<sub>2</sub> (dppe) to form the purple colored dimer  $[\text{TiCl}_3(\text{dppe})]_2$ , which converts reversibly into the green monomeric complex  $\text{TiCl}_3(\text{dppe})(\text{THF})$ . Most  $\text{Ti}^{\text{III}}$  complexes are susceptible to oxidation in air.

### 4.3 Titanium(IV) Complexes

As a result of the high ionic charge to radius ratio of titanium(IV), normal salts of titanium(IV) are difficult to prepare from aqueous solutions; these often yield basic, hydrolyzed species. A tris-catechol species,  $[\text{Ti}(\text{cat})_3]^{2-}$ , prepared by Raymond *et al.* is one exception: it is stable in aqueous solution up to pH 12.<sup>53</sup> The catechol ligand is so stabilizing to  $\text{Ti}^{\text{IV}}$  that the  $\text{Ti}^{\text{IV}}/\text{Ti}^{\text{III}}$  reduction potential is shifted from the value of +0.1 V cited as the standard potential in acid in Scheme 1 to a value for  $[\text{Ti}(\text{cat})_3]^{2-}$  of –1.14 V vs. NHE, affording a powerful example of ligand tuning of metal redox potential.

Several oxotitanium(IV) compounds have been isolated, and were originally thought to contain  $\text{TiO}^{2+}$  ions. This notion, however, seems to be incorrect, the compounds actually being polymeric in the solid state. For example,

$\text{TiOSO}_4\cdot\text{H}_2\text{O}$  consists of  $-\text{Ti}-\text{O}-\text{Ti}-\text{O}-$  chains, with each titanium being further coordinated to one water molecule and an oxygen from each of the three sulfates, giving a distorted octahedral geometry about the titanium. Similarly,  $\text{TiO}(\text{acac})_2$  is dimeric with a  $\text{Ti}(\mu\text{-O})_2\text{Ti}$  ring,<sup>54</sup> while the anion of  $(\text{NH}_4)_2\text{TiO}(\text{C}_2\text{O}_4)_2\cdot\text{H}_2\text{O}$  is tetrameric with a central eight-membered  $(-\text{Ti}-\text{O}-)_4$  ring.<sup>55</sup>

In contrast, studies on aqueous solutions of titanium(IV) in 2 M  $\text{HClO}_4$  are consistent with the presence of doubly charged cationic species. However, it is not clear whether the predominant species is  $[\text{TiO}]^{2+}$  or  $[\text{Ti}(\text{OH})_2]^{2+}$ .<sup>29</sup>

Complexes containing  $\text{Ti}=\text{O}$  bonds are rare, although a few, mainly with porphyrins, have been characterized, for example, (*meso*-DME) $\text{Ti}=\text{O}$ .<sup>56</sup> The  $\text{Ti}=\text{O}$  bonds appear to be short ( $\sim 1.62 \text{ \AA}$ ), while IR bands are in the region  $890\text{--}972 \text{ cm}^{-1}$ , which is consistent with a  $\text{Ti}=\text{O}$  double bond.<sup>57</sup>

The  $\text{Ti}^{\text{IV}}$  halides readily give adducts of stoichiometry  $\text{TiX}_4\text{L}_2$  and  $\text{TiX}_4(\text{L}-\text{L})$  with donor molecules, where L and L–L are mono- and bidentate ligands, respectively. The potentially bidentate ligand *o*-allylaniline reacts with  $\text{TiX}_4$  ( $\text{X} = \text{Cl}, \text{Br}$ ) but only complexes via the nitrogen atom, forming the pentacoordinate monomeric complexes  $\text{TiX}_4\text{L}$ .<sup>58</sup> Titanium(IV) is predicted to be a ‘hard’ acid, whereas titanium(III) might be expected to show intermediate ‘hard/soft’ behavior. However, contrary to expectation, titanium(IV) has sometimes been shown to prefer sulfur to oxygen as a donor atom, as evidenced by the Ti–S bonds in the 1,4-thiozen complexes  $\text{TiX}_4(\text{C}_4\text{H}_8\text{OS})_2$ .<sup>35</sup> Adducts of  $\text{TiOCl}_2$  with MeCN and  $\text{NMe}_3$  form  $\text{TiOCl}_2\text{L}_2$ ; when  $\text{L} = \text{NMe}_3$ , the complexes are monomeric, the IR spectra indicating the presence of a terminal  $\text{Ti}=\text{O}$  moiety ( $978 \text{ cm}^{-1}$ ), whereas the MeCN adduct is probably polymeric, presumably having a  $\text{Ti}-\text{O}-\text{Ti}$  bridge ( $\nu(\text{Ti}=\text{O})$  ca.  $890 \text{ cm}^{-1}$ ). Other complexes containing titanium in a trigonal bipyramidal geometry include the adduct formed from the reaction of  $\text{TiCl}_4$  and  $\text{N}(\text{SiMe}_3)_3$ , which has planar four-membered  $(\text{Ti}-\text{N})_2$  rings with planar geometry at N, apparently with considerable  $\pi$ -bonding in the rings. These are linked by chlorine bridges to give the five-coordinate titanium atoms.<sup>59</sup> In contrast, the reaction of  $\text{TiCl}_4$  with  $\text{Li}[\text{N}(\text{SiMe}_3)_2]$  yields  $[\text{TiCl}\{\text{N}(\text{SiMe}_3)_2\}_3]$ .<sup>60</sup> Steric crowding prevents complete substitution of the chlorine atoms, and the complex has a distorted tetrahedral structure.

Some of the most useful and thus widely studied complexes of titanium(IV) are the alkoxides.<sup>26,61</sup> The materials range from solids to volatile liquids that can be distilled or sublimed and that are readily soluble in organic solvents. The complexes are easily hydrolyzed, even by traces of moisture. The ease of hydrolysis decreases with the increasing chain length of the alkyl group. Such reactions yield polymeric species, which contain either  $-\text{OH}$  or  $-\text{O}-$  bridges.

The complexes are prepared by reacting sodium alkoxide with titanium tetrachloride in the appropriate alcohol (equation 8). An alternative method is shown in equation (9). If a proton-accepting reagent, such as ammonia, is not employed,

the reaction only proceeds as far as the  $\text{TiCl}_2(\text{OR})_2$  derivative. Compounds such as  $\text{Ti}(\text{OMe})_4$  are usually insoluble polymers, although a soluble tetramer,  $[\text{Ti}(\text{OMe})_4]_4$  (**8**), that has the same  $\text{M}_4\text{O}_{16}$  framework as  $[\text{Ti}(\text{OEt})_4]_4$  has been isolated. Both frameworks are centrosymmetric, containing six-coordinate titanium in a group of four edge-sharing octahedra.

In solution, the degree and type of polymerization is dependent on both the  $-\text{OR}$  group and the solvent. For example, in benzene, primary  $-\text{OR}$  groups give trimers, whereas secondary and tertiary  $-\text{OR}$  groups form only monomers. Few adduct complexes of  $\text{Ti}(\text{OR})_4$  are known.<sup>14</sup> An example is  $\text{Ti}_2(\text{OR})_8 \cdot \text{en}$  ( $\text{R} = \text{Et}$ ,  $i\text{-Pr}$ ), but the complexes almost completely dissociate in solution.<sup>14</sup> However,  $\text{Ti}(\text{OPh})_4$  readily forms 1:1 adducts with  $\text{PhOH}$ ,  $\text{NH}_3$ ,  $\text{NH}_2\text{Me}$ ,  $\text{NHMe}_2$ ,  $\text{NMe}_3$ ,  $\text{py}$ , dioxin,  $\text{PhNH}_2$ , and  $\text{Me}_2\text{CO}$ .<sup>62</sup>

The ready hydrolysis, particularly of the lower titanium alkoxides, has led to a number of interesting applications. They can be used to apply a thin, transparent, adherent surface coating of  $\text{TiO}_2$  to a variety of materials, including fabrics that require waterproofing, glass, and enamels, each of which become scratch resistant, and also in heat-resistant paints. The manufacture of paint provides the most important application of titanium alkoxides. When chelated with ligands such as  $\beta$ -diketonates, the resulting complexes  $[\text{Ti}(\text{OR})_2(\text{L-L})_2]$  are resistant to hydrolysis. Furthermore, the complexes are water-soluble and when used in concentrations of less than 1% form gels with the cellulose ether colloids used to thicken latex paints. These gels impart the required characteristics for thixotropic, or nondrip paints. The area of titanium alkoxides has been extensively reviewed by Bradley.<sup>61</sup>

A large number of bidentate and chelated titanium(IV) complexes have been prepared. By far, the greatest number of reports concern the  $\beta$ -diketonate complexes, which provide an extensive series of types  $\text{TiX}_3\text{L}$ ,  $\text{TiX}_4(\text{LH})$ ,  $\text{TiX}_2\text{L}_2$ ,  $[\text{TiL}_3]^+$ ,  $\text{TiOXL}$ , and  $[\text{TiOL}]_2$  ( $\text{L} = \beta$ -diketonate,  $\text{LH} = \beta$ -diketone).<sup>22</sup>

One bis( $\beta$ -diketonato) $\text{Ti}^{\text{IV}}$  compound (budotitane) (**9**) has demonstrated anticancer activity and has been tested in the treatment of colon cancer.<sup>63</sup> It and the more extensively studied organometallic compound  $\text{Cp}_2\text{TiCl}_2$  are thus potential anticancer therapeutics (see also *Metal-based Drugs*).<sup>63</sup>

A number of titanium(IV) complexes have been characterized in which titanium shows coordination numbers greater than six. Investigations of the diars complexes of the  $\text{Ti}^{\text{IV}}$  halides resulted in the first example of eight coordination in the first-row transition series.<sup>40</sup> In  $[\text{TiCl}_4(\text{diars})_2]$  (**10**), the dodecahedron contains two diars forming an elongated tetrahedron, and four chlorine atoms in a flattened tetrahedron with respect to the fourfold inversion axis.<sup>64</sup> Despite numerous attempts to prepare similar complexes with a range of other bidentate ligands, only those with the *o*-phenylene or a similar backbone have proved successful. Other diars complexes include  $[\text{TiX}_4(\text{diars})]$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ),  $[(\text{TiF}_4)_2(\text{diars})]$ , and  $[\text{TiI}_4(\text{diars})_2]$ .<sup>40</sup>

A large number of titanium(IV) phosphine complexes are known,<sup>40</sup> most being adducts of the tetrachloride  $\text{TiCl}_4(\text{PR}_3)_2$ , although  $\text{TiBr}_4(\text{PPh}_3)$  and  $\text{TiBr}_4(\text{PPh}_3)_2$  have also been reported.<sup>65</sup> The former has  $\text{C}_{3v}$  symmetry, whereas the latter has a cis octahedral structure. There is some evidence for the existence of the dinuclear species  $\text{Ti}_2\text{Cl}_2(\text{PR}_3)_4$ .<sup>40</sup> There is a paucity of well-characterized arsine and stilbine complexes. Thus, it seems quite surprising that a large number of patents have dealt with catalyst systems employing these compounds in the polymerization and oligomerization of alkenes.<sup>26</sup>

A further example of an eight-coordinate dodecahedral complex of titanium(IV) is the volatile, anhydrous  $\text{Ti}(\text{NO}_3)_4$  in which the nitrate groups are bidentate, coordinating through two oxygen atoms (**11**). The nitrate groups are arranged symmetrically about the metal atom with  $D_{2d}$  symmetry in a flattened tetrahedral manner.<sup>66</sup>

There has been a great deal of interest in the complexes of 1,2-dithiolenes and 1,1-dithiolato complexes, which arises

not only from their industrial applications but also from the bonding in the complexes.<sup>26</sup> The X-ray crystal structure of  $\text{Ti}(\text{S}_2\text{CNET}_2)_4$  shows it to contain discrete eight-coordinate molecules.<sup>67</sup> Furthermore,  $\text{TiCl}(\text{S}_2\text{CNMe}_2)_3$  has been shown by X-ray crystallography to be seven coordinate (12).<sup>68</sup> The molecule has a pentagonal bipyramidal structure with the chlorine atom in the axial position. Prior to this structure elucidation, the existence of seven-coordinate titanium(IV) was uncertain.<sup>68</sup>

Fay and coworkers<sup>68</sup> have prepared a series of  $\text{Ti}(\text{S}_2\text{CNR}_2)_n\text{Cl}_{4-n}$  compounds ( $n = 2, 3, 4$ ;  $\text{R} = \text{Me}, i\text{-Pr}, i\text{-Bu}$ ; or  $n = 3$ ,  $\text{R} = \text{Et}$ ) by reacting  $\text{TiCl}_4$  with anhydrous sodium  $N,N$ -dialkyldithiocarbamates in  $\text{CH}_2\text{Cl}_2$  or benzene. The complexes are monomeric and nonelectrolytes. Thus when  $n = 2, 3$ , or  $4$ , the titanium atom exhibits coordination numbers of six, seven, and eight respectively. These workers have also studied the monothiocarbamate complexes  $\text{Ti}(\text{R}_2\text{mtc})_4$ .<sup>69</sup> The complexes are shown by  $^1\text{H}$  NMR and X-ray diffraction to be eight-coordinate dodecahedra, which have an all-cis structure with four sulfur atoms on one side and four oxygen atoms on the other.

Reaction of aqueous solutions of titanium(IV) complexes with  $\text{H}_2\text{O}_2$  results in an intense orange color. This color can be used analytically to determine titanium. It is due to the formation of the stable peroxo species  $[\text{Ti}(\text{O}_2)(\text{OH})]^+$ .<sup>70</sup> There is a great deal of interest in peroxo complexes of titanium(IV) macrocycles and porphyrins.<sup>26</sup> Such complexes are readily oxidized to the corresponding peroxo complex by oxidizing the (por)TiO (por = porphyrin) complex to (por)Ti(O<sub>2</sub>) with  $\text{H}_2\text{O}_2$  or benzoyl peroxide.<sup>71</sup> The crystal structure of the octaethylporphyrin-derived (OEP)Ti(O<sub>2</sub>) (13) is typical:  $\text{Ti}-\text{O}(1) = 1.822 \text{ \AA}$ ,  $\text{Ti}-\text{O}(2) = 1.827 \text{ \AA}$ , and  $\text{O}-\text{O} = 1.445 \text{ \AA}$ .

## Abbreviations

Cryptand = 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane; Ind =  $\eta^5$ -indenyl; Trmpe = 1,1,1-tris(dimethylphosphinomethyl)ethane; tritox =  $(t\text{-Bu}_3\text{C})_3\text{CO}^-$ .

## 1 INTRODUCTION

The majority of titanium organometallic chemistry involves complexes in which the titanium is in its highest oxidation state (+4) and cyclopentadienyl (*see Cyclopentadienyl*) derivatives serve as ancillary ligands. However, considerable chemistry has also been developed in which the titanium is in the +3 and +2 oxidation state, with lesser amounts of chemistry known for titanium in lower oxidation states (+1, 0). Since the early 1980s, chemists have placed considerable emphasis on the fine-tuning of the structure and reactivity of titanium organometallic

complexes. Particular emphasis has been devoted to tailoring the structure and reactivity of bis(cyclopentadienyl)titanium derivatives by incorporating electron-donating, electron-withdrawing, sterically demanding, bridging (constrained geometry), or chiral substituents on the cyclopentadienyl ring. Additional efforts at modifying the structure and reactivity have focused on varying the oxidation state or coordination geometry at the titanium center. Titanium organometallic chemistry through 1980 has been extensively reviewed by Bottrill, Gavens, Kelland, and McMeeking.<sup>1</sup> Several other articles in this encyclopedia are based on the application of titanium organometallic chemistry to catalysis and organic synthesis (*see Asymmetric Synthesis by Homogeneous Catalysis*; *Metathesis Polymerization Processes by Homogeneous Catalysis*; and *Oligomerization & Polymerization by Homogeneous Catalysis*).

## 2 CARBONYL AND PHOSPHINE COMPLEXES WITHOUT $\pi$ -LIGANDS

The hypothetical titanium heptacarbonyl  $\text{Ti}(\text{CO})_7$  is as yet unknown. However,  $\text{Ti}(\text{CO})_6$  has been prepared and characterized by matrix isolation techniques.  $\text{Ti}(\text{CO})_6$ , thus prepared, is found to be unstable above  $-200^\circ\text{C}$ .<sup>2</sup> Titanium carbonyls  $\text{Ti}(\text{CO})_x$  ( $x = 1-6$ ) are formed during deposition of laser-ablated titanium atoms with CO during condensation in excess Ne, or on annealing and photolysis of the matrix.<sup>3</sup> Titanium carbonyl complexes (*see Carbonyl Complexes of the Transition Metals*) have also been observed spectroscopically (by IR) as intermediates in the low-temperature reaction of  $\text{Ti}(\text{CH}_2\text{Ph})_4$  and its dicyclohexylamine adduct with CO.<sup>4</sup>

Reduction of  $\text{TiCl}_4(\text{THF})_2$  with sodium naphthalenide in the presence of 2.1–2.3 equivalent of dmpe in THF at  $-70$  to  $-80^\circ\text{C}$  followed by treatment with CO at 1 atm gives  $\text{Ti}(\text{CO})_3(\text{dmpe})_2$  as shown in (equation 1). Treatment of  $\text{Ti}(\text{CO})_5(\text{dmpe})_2$  with CO at room temperature gives  $\text{Ti}(\text{CO})_5(\text{dmpe})$ .<sup>5</sup>  $\text{Ti}(\text{CO})_3(\text{dmpe})_2$  is monomeric in the solid state, possessing a monocapped octahedral structure. One of the carbonyls in  $\text{Ti}(\text{CO})_3(\text{dmpe})_2$  can be replaced by treatment with  $\text{PF}_3$  to give  $\text{Ti}(\text{CO})_2(\text{PF}_3)(\text{dmpe})_2$ .<sup>6</sup>

Ellis and coworkers have found  $\text{Ti}(\text{CO})_5(\text{dmpe})$  to be much more reactive than  $\text{Ti}(\text{CO})_3(\text{dmpe})_2$ , and have found that it can serve as a synthetic equivalent for  $\text{Ti}(\text{CO})_7$ . Reaction of  $\text{Ti}(\text{CO})_5(\text{dmpe})$  with NaCp, NaInd, or  $\text{K}[(\text{HB}(\text{pz})_3)]$  leads to loss of one carbonyl and dmpe to give the corresponding anionic complexes  $[\text{CpTi}(\text{CO})_4]^-$  (equation 2),  $[\text{IndTi}(\text{CO})_4]^-$ , and  $[\text{HB}(\text{pz})_3\text{Ti}(\text{CO})_4]^-$ , respectively, in 70–80% yield. Treatment of  $\text{Ti}(\text{CO})_5(\text{dmpe})$  with  $\text{NaEPh}_3$

(E = Ge, Sn) results in loss of one CO to give the corresponding anionic complexes  $[\text{Ti}(\text{CO})_4(\text{dmpe})(\text{EPh}_3)]^-$ . Treatment of  $\text{Ti}(\text{CO})_5(\text{dmpe})$  with the tridentate ligand *trmpe* gives  $\text{Ti}(\text{CO})_4(\text{trmpe})$ .<sup>5</sup>  $\text{Ti}(\text{CO})_4(\text{trmpe})$  has also been prepared directly by the treatment of  $\text{TiCl}_4(\text{THF})_2$  with potassium naphthalenide in the presence of CO and *trmpe*.<sup>7</sup>

Ellis and coworkers have extensively studied the chemistry of hexacarbonyltitanate(2-),  $[\text{Ti}(\text{CO})_6]^{2-}$ . Reductive carbonylation (see *Reductive Carbonylation*) of  $\text{Ti}(\text{CO})_4(\text{trmpe})$  with (cryptand 2,2,2)potassium naphthalenide at  $-70^\circ\text{C}$  followed by warming to room temperature gives the thermally robust  $[\text{K}(\text{cryptand } 2.2.2)]_2[\text{Ti}(\text{CO})_6]$  in quantitative yield.<sup>8</sup> Treatment of  $\text{Ti}(\text{CO})_6^{2-}$  with azobenzene gives  $[\text{Ti}(\text{PhN}=\text{NPh})(\text{CO})_4]^{2-}$  (equation 3) in 40–65% yield. Hydrolysis of  $[\text{Ti}(\text{PhN}=\text{NPh})(\text{CO})_4]^{2-}$  gives 1,2-diphenylhydrazine and the hydroxo-carbonyl titanium complex,  $[\text{Ti}_2(\mu\text{-OH})_2(\text{CO})_8]^{2-}$  (equation 3), which was structurally characterized as the  $[\text{K}(18\text{-crown-6})]^+$  salt.<sup>9</sup>

Reaction of  $[\text{Ti}(\text{CO})_6]^{2-}$  with MeOH and PhOH gives the metal-carbonyl dimers  $[\text{Ti}(\text{CO})_4(\mu\text{-OR})_2]^{2-}$  (R = Me, Ph). The structure and reactivity of these complexes suggest that the bridging alkoxy ligands function as  $\pi$ -donors satisfying the electronic requirements of each titanium.<sup>10</sup> Reaction of  $\text{BH}_3 \cdot \text{THF}$  with  $[\text{K}(15\text{-crown-5})_2]_2[\text{Ti}(\text{CO})_6]$  or  $[\text{K}(18\text{-crown-6})_2]_2[\text{Ti}(\text{CO})_6]$  gives  $[\text{K}(15\text{-crown-5})_2]_2[\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]$  and  $[\text{K}(18\text{-crown-6})][\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]^-$  respectively. Treatment of  $[\text{K}(15\text{-crown-5})_2]_2[\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]$  with  $\text{KC}_4\text{H}_4\text{N}$  gives  $[\text{K}(15\text{-crown-5})_2]_2[(\eta^5\text{-C}_4\text{H}_4\text{N})\text{Ti}(\text{CO})_4]$ .<sup>11</sup>

Treatment of  $\text{Ti}(\text{CO})_6^{2-}$  with  $\text{R}_3\text{SnCl}$  (R = Me, Ph, cyclohexyl) in THF gives the thermally stable  $\text{R}_3\text{SnTi}(\text{CO})_6^-$  salts in 70–80% isolated yields.<sup>12</sup> In an analogous manner, reaction of  $\text{Ti}(\text{CO})_6^{2-}$  with  $\text{ClC}(p\text{-C}_6\text{H}_4\text{R})_3$  (R = H, OCH<sub>3</sub>) in THF gives  $\text{Ti}(\text{CO})_4[\eta^5\text{-C}(p\text{-C}_6\text{H}_4\text{R})_3]$  in 28–30% yields.<sup>13</sup>

The reduction of  $\text{TiI}_4$  with 1 equivalent of Na/Hg amalgam in the presence of  $\text{PMe}_3$  gives the biotetrahedral complex  $\text{Ti}_2\text{I}_6(\text{PMe}_3)_4$ . The Ti–Ti distance of 4.30 Å in  $\text{Ti}_2\text{I}_6(\text{PMe}_3)_4$  clearly indicates the absence of a Ti–Ti bond.<sup>14</sup>

Treatment of *trans*- $\text{TiX}_2(\text{dmpe})_2$  (X = Cl, Br) with CO at low temperature gives the thermally unstable  $\text{TiX}_2(\text{CO})_2(\text{dmpe})_2$ . In an analogous manner, treatment of the mixed halide complex  $\text{TiClBr}(\text{dmpe})_2$  with CO gives the corresponding dicarbonyl complex  $\text{TiClBr}(\text{CO})_2(\text{dmpe})_2$ . NMR experiments suggest that these complexes adopt a bicapped octahedral structures, with the halide ligands in the capping sites and the carbonyl ligands mutually *cis*.<sup>15</sup>

Reaction of benzylbis(2-ethoxyethyl) phosphine ( $\text{PhCH}_2\text{P}(\text{CH}_2\text{CH}_2\text{OEt})_2$ ) with  $\text{TiCl}_4$  gives  $\text{TiCl}_4[\text{PhCH}_2\text{P}(\text{CH}_2\text{CH}_2\text{OEt})_2]$  (**1**). The crystal structure of  $\text{TiCl}_4[\text{PhCH}_2\text{P}(\text{CH}_2\text{CH}_2\text{OEt})_2]$  shows the metal to have a distorted octahedral

geometry, where the ligand acts as a P,O-bonding chelate ligand (see *Chelating Ligands*).<sup>16</sup> Treatment of  $\text{TiI}_4$  with one equivalent of the bidentate ligands *o*-( $\text{PMe}_2$ )<sub>2</sub> $\text{C}_6\text{H}_4$  and *o*-( $\text{AsMe}_2$ )<sub>2</sub> $\text{C}_6\text{H}_4$  in anhydrous  $\text{CH}_2\text{Cl}_2$  gives  $\text{TiI}_4(o\text{-(PMe}_2)_2\text{C}_6\text{H}_4)$  and  $\text{TiI}_4(o\text{-(AsMe}_2)_2\text{C}_6\text{H}_4)$  (**2**), respectively.<sup>17</sup>

The reactions of 1,5,9-triethyl-1,5,9-triphosphacyclodecane,  $[\text{12}] \text{aneP}_3\text{Et}_3$ , with  $\text{TiCl}_3 \cdot \text{THF}$  gives  $\text{TiCl}_3([\text{12}] \text{aneP}_3\text{Et}_3)$  (**3**).<sup>18</sup>

### 3 CARBONYL, PHOSPHINE, ALKENE, AND ALKYNE COMPLEXES WITH $\pi$ -LIGANDS

The cyclopentadienyl titanium carbonyl anions  $[\text{CpTi}(\text{CO})_4]^-$  and  $[\text{Cp}^*\text{Ti}(\text{CO})_4]^-$  have been prepared and extensively studied by Ellis and coworkers.<sup>19</sup> Reduction of  $\text{CpTiCl}_3$  or  $\text{Cp}^*\text{TiCl}_3$  with alkali-metal naphthalenide at low temperature under a CO atmosphere followed by cation exchange gives  $[\text{Et}_4\text{N}][\text{CpTi}(\text{CO})_4]$  (equation 4) and  $[\text{Et}_4\text{N}][\text{Cp}^*\text{Ti}(\text{CO})_4]$ , respectively, in moderate yield. X-ray crystallographic analysis of  $[\text{Ph}_4\text{As}][\text{CpTi}(\text{CO})_4]$  indicates that  $[\text{CpTi}(\text{CO})_4]^-$  is isostructural with the neutral isoelectronic vanadium complex  $\text{CpV}(\text{CO})_4$  (see *Vanadium: Organometallic Chemistry*). The unsolvated  $\text{Na}[(\text{C}_5\text{H}_5)\text{Ti}(\text{CO})_4]$  was found to be explosive at room temperature. Treatment of  $[\text{CpTi}(\text{CO})_4]^-$  with  $\text{Ph}_3\text{SnCl}$  or  $\text{Ph}_3\text{PAuCl}$  gives the corresponding heterobimetallic titanium(II) complexes  $\text{CpTi}(\text{CO})_4\text{E}$  (E =  $\text{Ph}_3\text{Sn}$ ,  $\text{Ph}_3\text{PAu}$ ).<sup>20–22</sup>

The zerovalent cyclopentadienyl (see *Cymantrene*) titanium carbonyl phosphine complexes  $[\text{CpTi}(\text{CO})_3(\text{PR}_3)]^-$  and

$[\text{Cp}^*\text{Ti}(\text{CO})_3(\text{PR}_3)]^-$  ( $\text{R} = \text{Me}, \text{Ph}$ ) are prepared by the photo substitution reactions of  $[\text{CpTi}(\text{CO})_4]^-$  and  $[\text{Cp}^*\text{Ti}(\text{CO})_4]^-$ , respectively, with phosphine ligands. The analogous dmpe complexes  $[\text{CpTi}(\text{CO})_2(\text{dmpe})]^-$  and  $[\text{Cp}^*\text{Ti}(\text{CO})_2(\text{dmpe})]^-$  are prepared by the reductive cleavage of  $\text{Cp}_2\text{Ti}(\text{CO})_2$  and  $\text{Cp}_2^*\text{Ti}(\text{CO})_2$  in the presence of dmpe. Protonation of the  $[\text{CpTi}(\text{CO})_3(\text{PR}_3)]^-$  and  $[\text{Cp}^*\text{Ti}(\text{CO})_3(\text{PR}_3)]^-$ , gives the thermally unstable carbonyl hydrides  $\text{CpTi}(\text{CO})_3(\text{PR}_3)\text{H}$  and  $\text{Cp}^*\text{Ti}(\text{CO})_3(\text{PR}_3)\text{H}$ , respectively. However, protonation of the analogous  $[\text{Cp}^*\text{Ti}(\text{CO})_2(\text{dmpe})]^-$  gives  $\text{Cp}^*\text{Ti}(\text{CO})_2(\text{dmpe})\text{H}$  which could be isolated at room temperature.<sup>23</sup>

Treatment of  $(\text{CpTiCl}_2)_x$  with 1 equivalent or BuLi in the presence of dmpe in ether gives the diamagnetic  $\text{CpTiCl}(\text{dmpe})_2$ , which upon treatment with MeLi or BuLi gives  $\text{CpTiMe}(\text{dmpe})_2$  and  $\text{CpTiH}(\text{dmpe})_2$ , respectively.<sup>24</sup>

Addition of  $\text{BH}_3 \cdot \text{THF}$  to  $[\text{K}(\text{15-crown-5})_2][\text{Ti}(\text{CO})_6]$  and  $[\text{K}(\text{18-crown-6})_2][\text{Ti}(\text{CO})_6]$  gives  $[\text{K}(\text{15-crown-5})_2][\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]$  and  $[\text{K}(\text{18-crown-6})_2][\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]^-$ . Treatment of  $[\text{K}(\text{15-crown-5})_2][\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]$  with potassium-pyrrole gives  $[\text{K}(\text{15-crown-5})_2][(\eta^5\text{-C}_4\text{H}_4\text{N})\text{Ti}(\text{CO})_4]$ .<sup>25</sup>

Reduction of  $(\eta^5\text{-C}_5\text{Me}_5)\text{TiCl}_3$  with sodium naphthalenide at  $-60^\circ\text{C}$  in DME in the presence of dmpe, followed by carbonylation at one atm, gives the unstable olive-green complex  $(\eta^5\text{-C}_5\text{Me}_5)\text{Ti}(\text{CO})(\text{dmpe})\text{Cl}$  which has been characterized in solution by NMR and IR.<sup>26</sup>

#### 4 ALKYL AND ARYL COMPLEXES WITHOUT $\pi$ -LIGANDS

The synthesis and reactivity of  $\sigma$ -bonded alkyl (*see Alkyl Complexes*) and aryl titanium(IV) complexes has been extensively reviewed by Bottrill *et al.*<sup>27</sup>

Dialkyltitanium complexes have long been proposed as intermediates in the thermal and photochemical decomposition of tetraalkyltitanium complexes. Treatment of  $\text{TiCl}_2(\text{dmpe})_2$  with alkylolithium reagents gives mixed alkyl/halide products caused by incomplete exchange of the strongly held Cl.<sup>28</sup> However, treatment of  $\text{TiCl}_2(\text{dmpe})_2$  with an excess of  $\text{LiBH}_4$  forms paramagnetic  $\text{Ti}(\eta^2\text{-BH}_4)_2(\text{dmpe})_2$ , which upon treatment with MeLi gives  $\text{TiMe}_2(\text{dmpe})_2$  (equations 5 and 6). Surprisingly,  $\text{TiMe}_2(\text{dmpe})_2$  is found to be diamagnetic, and could be characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR. Single-crystal X-ray and neutron diffraction studies have been carried out on  $\text{TiMe}_2(\text{dmpe})_2$  at 173 and 30 K, respectively. The titanium center in  $\text{TiMe}_2(\text{dmpe})_2$  adopts a regular octahedral structure with the methyl groups trans to each other. The Ti–C–H bond angles are all found to be  $109^\circ\text{C}$  or greater, indicating no agostic bonding (*see Agostic Bonding*) in the solid state.<sup>29</sup>

Treatment of  $\text{TiCl}_4$  with one equivalent of dmpe gives  $\text{TiCl}_4(\text{dmpe})$ . This complex can be readily alkylated with 1 or 2 equivalent of  $\text{PhCH}_2\text{MgCl}$  to give  $\text{TiCl}_3(\text{PhCH}_2)(\text{dmpe})$  and  $\text{TiCl}_2(\text{PhCH}_2)_2(\text{dmpe})$ , respectively. The corresponding thermally unstable mono *t*-butyl complex,  $\text{TiCl}_3(t\text{-Bu})(\text{dmpe})$ , decomposes to give the dinuclear edge-sharing Ti(III) complex,  $\text{Ti}_2\text{Cl}_4(\mu\text{-Cl})_2(\text{dmpe})_2$ . The analogous,  $\text{Ti}_2\text{Cl}_4(\mu\text{-Cl})_2(\text{depe})_2$  was prepared directly by the reaction of  $\text{TiCl}_3(\text{THF})_3$  with the corresponding phosphine. Thermal decomposition of the thermally unstable di-*t*-butyl complex  $\text{TiCl}_2(t\text{-Bu})_2(\text{dmpe})$  gives  $\text{Ti}_3\text{Cl}_6(\text{dmpe})_3$ , which consists of an equilateral triangle of Ti(II) atoms with three coplanar  $\mu\text{-Cl}$  atoms bridging the edges. Each Ti atom is further coordinated by a chelating dmpe ligand and a chloride ion, with Ti–Ti distances of  $2.872(3) \text{ \AA}$ .<sup>30</sup>

Highly sterically hindered alkyl complexes  $(\text{Me}_3\text{CCH}_2)_3\text{TiSi}(\text{SiMe}_3)_3$  and  $(\text{Me}_3\text{SiCH}_2)_3\text{TiSi}(\text{SiMe}_3)_3$  were prepared by the reaction of  $(\text{Me}_3\text{CCH}_2)_3\text{TiCl}$  and  $(\text{Me}_3\text{SiCH}_2)_3\text{TiCl}$ , respectively, with  $\text{LiSi}(\text{SiMe}_3)_3(\text{THF})_3$ . The structures of  $(\text{Me}_3\text{CCH}_2)_3\text{TiSi}(\text{SiMe}_3)_3$  and  $(\text{Me}_3\text{SiCH}_2)_3\text{TiSi}(\text{SiMe}_3)_3$  were determined by X-ray diffraction show that the three alkyl groups on the metal centers are staggered with respect to the trimethylsilyl groups on the central silicon atoms.<sup>31</sup>

Dialkyltitanium(IV) complexes  $\text{R}_2\text{TiX}_2$  ( $\text{R} = \text{Bu}, i\text{Pr}$ ,  $\text{X} = \text{Cl}, \text{O}i\text{Pr}$ ), react with olefins, acetylenes, azoarenes, aldehydes, ketones, amides, and imines, to undergo in high-yield epimetallation of the multiple bond with  $\text{TiX}_2$  giving transient 3-membered titanacycles. Treatment of alkynes with  $\text{R}_2\text{TiX}_2$  followed by hydrolytic work-up gave cis-alkenes with high selectivity. In a similar manner treatment of benzophenone with  $\text{R}_2\text{TiX}_2$  followed by hydrolytic work-up gave benzopinacol and benzhydrol.<sup>32</sup>

#### 5 ALKYLIDENE AND TITANACYCLOBUTANE COMPLEXES

Tebbe's Reagent (*see Tebbe's Reagent*), a stable, soluble dimethylaluminum chloride–titanocene methylidene complex, is prepared from  $\text{Cp}_2\text{TiCl}_2$  and  $(\text{AlMe}_3)_2$ , as shown in equation (7). Tebbe's reagent has been successfully utilized as an alkene metathesis (*see Metathesis*) catalyst and readily adds methylene to aldehydes, ketones, and esters. Treatment of Tebbe's reagent, in the presence of base, with alkenes or alkynes leads to titanacyclobutanes or titanacyclobutenes, as shown in Scheme 1. For monosubstituted titanacyclobutanes, the substituent prefers the  $\beta$ -position. Addition of a second  $\beta$  substituent to the metallacycles (*see Metallacycle*) results in significant destabilization of the metallacycles.<sup>33</sup> Bickelhaupt and coworkers have developed an alternative preparation for  $[\text{Cp}_2\text{Ti}=\text{CH}_2]$ . Thus, treatment of  $\text{Cp}_2\text{TiCl}_2$  with  $(\text{BrMg})_2\text{CH}_2$  gives  $[\text{Cp}_2\text{Ti}=\text{CH}_2]$ , which reacts with alkenes and alkynes to give titanacyclobutane and titanacyclobutene complexes in

a manner similar to that of Tebbe's reagent.<sup>34</sup>

Metal alkylidene complexes (see *Schrock-type Carbene Complexes*) have been proposed as intermediates in many catalytic reactions, including alkene metathesis (see *Organic Synthesis Using Metal-mediated Metathesis Reactions*), alkene and alkyne polymerization, methylenation of carbonyl compounds, and cyclopropanation of alkenes.<sup>35–39</sup>

Titanacyclobutanes serve as ready sources of  $[\text{Cp}_2\text{Ti}=\text{CH}_2]$ , reacting with alkenes and alkynes to give titanacyclobutane and titanacyclobutene complexes, as shown in Scheme 2, via slow formation of an alkene–methylidene intermediate which is rapidly trapped by the alkene or alkyne (equation 8). Titanacyclobutanes also transfer methylene groups to carbonyl groups, effect ring-opening polymerization of strained

Scheme 1

Scheme 2

Scheme 3

cyclic alkenes (see *Ring Opening Metathesis Polymerization Reactions*), and form dinuclear methylene complexes (Scheme 3).<sup>35,36,39</sup>

(8)

Titanocene methylidene phosphine complexes  $\text{Cp}_2\text{Ti}=\text{CH}_2\text{L}$  ( $\text{L} = \text{PMe}_3, \text{PMe}_2\text{Ph}, \text{PEt}_3$ ) have been generated by the thermolysis of titanocene metallacyclobutanes in the presence of excess phosphine (equation 9). These titanocene methylidene phosphine complexes have been found to react with alkenes, alkynes, and CO to form metallacyclobutanes, metallacyclobutenes, and a ketene complex, respectively. The phosphine ligand is labile, and an equilibrium mixture is rapidly established if a second phosphine is added.<sup>40</sup>

(9)

Treatment of  $\text{Cp}^*_2\text{TiCl}_2$  with 2 equivalents of vinyl lithium gives the corresponding divinyl complex  $\text{Cp}^*_2\text{Ti}(\text{CH}=\text{CH}_2)_2$  at low temperature. However, at room temperature,  $\text{Cp}^*_2\text{Ti}(\text{CH}=\text{CH}_2)_2$  undergoes rearrangement quantitatively to give a titanacyclobutane with an exocyclic methylidene group (4) (equation 10).<sup>41,42</sup>

(10)

Migratory insertion (see *Migratory Insertion*) reaction of isonitriles,  $\text{RN}\equiv\text{C}$ , ( $\text{R} = \text{C}_6\text{H}_{11}, t\text{-Bu}$ ) with 3-isopropylbis(pentamethylcyclopentadienyl)titanacyclobutane (5) gives the iminoacyl titanium complexes (6) ( $\text{R} = t\text{-Bu}$ , cyclohexyl) in 90–92%. Treatment of (6) ( $\text{R} = \text{C}_6\text{H}_{11}$ ) with  $\text{CH}_2=\text{CH}_2$  in toluene at 10 psi gave 94% cyclobutanamine (7). Treatment of (6) ( $\text{R} = \text{C}_6\text{H}_{11}, t\text{-Bu}$ ) with 60 psi of CO at  $-78^\circ\text{C}$  gives the  $\text{Cp}^*_2\text{Ti}$ cyclopentenamidolate complex in

high yield.<sup>43</sup>

Addition of aryldiazoalkanes to  $\text{Cp}_2^*\text{Ti}(\text{C}_2\text{H}_4)$  gives  $\eta^2$ - $\text{N}_2$ -titanium aryldiazoalkane complexes  $\text{Cp}_2^*\text{Ti}(\text{N}_2\text{CHAr})$ . Unlike most diazoalkane complexes, they release dinitrogen thermally to give transient carbene complexes which when trapped with styrene gives the titanacyclobutane complexes  $\text{Cp}_2^*\text{Ti}(\text{CHArCHPhCH}_2)$ . The addition of  $t\text{-BuN}\equiv\text{C}$  results in a coordination change of the diazoalkane fragment from  $\eta^2$  to  $\eta^1$  to give  $\text{Cp}_2^*\text{Ti}(\eta^1\text{-N}^2\text{CHPh})(t\text{-BuN}\equiv\text{C})$ . The bound  $t\text{-BuN}\equiv\text{C}$  ligand exchanges with free  $t\text{-BuN}\equiv\text{C}$  in solution.<sup>44</sup>

Addition of (trimethylsilyl)diazomethane to  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-C}_2\text{H}_4)$  gives the  $\eta^2$ - $\text{N}_2$ -diazoalkane complex  $\text{Cp}_2^*\text{Ti}(\text{N}_2\text{CHSiMe}_3)$ .  $\text{Cp}_2^*\text{Ti}(\text{N}_2\text{CHSiMe}_3)$  loses  $\text{N}_2$  in solution under mild conditions to give the fulvene complex  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{TiCH}_2\text{SiMe}_3$ . Thermolysis of  $\text{Cp}_2^*\text{Ti}(\text{N}_2\text{CHSiMe}_3)$  in the presence of 1-alkenes yields the trans- $\alpha$ ,  $\beta$ -disubstituted titanacyclobutane complexes  $\text{Cp}_2^*\text{Ti}(\text{CH}(\text{SiMe}_3)\text{CH}(\text{R})\text{CH}_2)$ .<sup>45</sup>

The titanocene vinylidene intermediate  $\text{Cp}_2^*\text{Ti}(=\text{C}=\text{CH}_2)$  formed by ethane or methane elimination from titanacyclobutane (4) or  $\text{Cp}_2^*\text{Ti}(\text{CH}=\text{CH}_2)\text{Me}$ , respectively, reacts with isothiocyanates,  $\text{RNCS}$  ( $\text{R} = \text{C}_6\text{H}_{11}$ ,  $\text{Ph}$  or  $t\text{-Bu}$ ), by a  $[2+2]$  cycloaddition, to give the titanathietane complexes (8). In all cases, the regioisomer in which the S atom is bonded to Ti is found as the primary product. Upon heating in the presence of pyridine, a rearrangement of (8) to the regioisomeric titanacyclobutane derivative (9) was observed (equation 12).<sup>46</sup>

Treatment of  $\text{Cp}^*(\text{C}_5\text{Me}_4\text{CH}_2)\text{TiCl}$  with 2-methylallyl Grignard gives to  $\text{Cp}^*(\eta^5\text{-}\eta^2\text{-C}_5\text{Me}_4\text{CH}_2\text{CMe}(\text{CH}_2)_2)\text{Ti}$  (10), with a titanacyclobutane tethered to the  $\text{Cp}^*$  ligand by a

methylene bridge. Thermolysis of (10) gives a new fulvene complex  $(\text{C}_5\text{Me}_4\text{CH}_2)(\eta^5\text{-}\eta^1\text{-C}_5\text{Me}_4\text{CH}_2\text{CMe}_2\text{CH}_2)\text{Ti}$ .<sup>47</sup>

$\alpha$ -H elimination (see  *$\alpha$ -Elimination*) from  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{Ti}(\text{CH}=\text{CH}_2)(\text{CH}_3)$  gives  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{Ti}=\text{C}=\text{CH}_2$ , which further reacts to give the fulvene complexes  $(\text{C}_5\text{Me}_3(\text{CH}_2\text{CH}_2\text{NMe}_2)\text{CH}_2)\text{TiCH}=\text{CH}_2$  and  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)(\text{C}_5\text{Me}_4\text{CH}_2)\text{TiCH}=\text{CH}_2$ . The analogous  $\alpha$ -H elimination from  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{Ti}(\text{CH}=\text{CH}_2)_2$  gives  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{Ti}=\text{C}=\text{CH}_2(\eta^2\text{-CH}_2=\text{CH}_2)$ , which rearranges to a titanacyclobutane with an exocyclic methylenide group analogous to (4).<sup>48</sup>

## 6 DIENE COMPLEXES LACKING OTHER $\pi$ -LIGANDS

The homoleptic (see *Homoleptic Compound*) titanium diene complex  $(\eta^4\text{-}t\text{-BuCH}=\text{CHCH}=\text{CHBu-}t)\text{Ti}$  (11) has been prepared by the condensation of electron-beam vaporized titanium with an excess of 1,4-di-*t*-butylbuta-1,3-diene<sup>49</sup> (see *Metal Vapor Synthesis of Transition Metal Compounds*). The bis-diene dmpe complex  $\text{Ti}(\text{dmpe})(\eta^4\text{-C}_4\text{H}_6)_2\text{Ti}$  (12) has been prepared by the reduction of  $\text{TiCl}_4(\text{dmpe})$  with  $\text{Na/Hg}$  in the presence of butadiene, and by the reduction of  $\text{TiCl}_4$  with  $\text{CH}_2=\text{CHLi}$  in the presence of dmpe.<sup>50-52</sup>

Reaction of *trans*- $\text{TiMe}_2(\text{dmpe})_2$  with 1,3-butadiene and *trans*, *trans*-1,4-diphenyl-1,3-butadiene at  $-20^\circ\text{C}$  give the titanium(II) butadiene complexes  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_6)(\text{dmpe})$  and  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_4\text{Ph}_2)(\text{dmpe})$ , respectively. The NMR of spectra  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_6)(\text{dmpe})$  and  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_4\text{Ph}_2)(\text{dmpe})$  are consistent with structures in which the Me groups are mutually *cis*, which was verified by X-ray crystallography

for the  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_4\text{Ph}_2)(\text{dmpe})$ . These molecules are fluxional on the NMR timescale ( $\Delta H^\ddagger = 9.1 \pm 0.2$  kcal/mol and  $\Delta S^\ddagger = 3 \pm 1$  eu) for  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_4\text{Ph}_2)(\text{dmpe})$ . When the reaction of  $\text{TiMe}_2(\text{dmpe})_2$  and 1,3-butadiene was allowed to continue at  $-20^\circ\text{C}$  for more than 12 h, a second titanium complex is formed, which has been identified as (1-octa-1,6-diene-1,8-diyl)  $(\text{TiMe}_2)_3$ , (1-octa-1,6-diene-1,8-diyl)(dmpe). Both  $\text{Ti}(\eta^4\text{-C}_4\text{H}_6)_2(\text{dmpe})$  and  $\text{TiMe}_2(\eta^4\text{-C}_4\text{H}_4\text{Ph}_2)(\text{dmpe})$  exhibit the butadiene ligands bound as true dienes, unlike the structure observed for many other early transition metal butadiene complexes.<sup>53</sup>

## 7 DIENE COMPLEXES CONTAINING OTHER $\pi$ -LIGANDS

Mixed cyclopentadienyl–diene titanium complexes,  $\text{Cp}^*\text{TiX}(\text{diene})$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ), have been prepared in 30–60% yield by the stoichiometric reaction of  $\text{Cp}^*\text{TiX}_3$  with (2-butene-1,4-diyl)magnesium derivatives or by the reduction of  $\text{Cp}^*\text{TiX}_3$  with  $\text{RMgX}$  ( $\text{R} = i\text{-Pr}, t\text{-Bu}, \text{Et}$ ;  $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) in the presence of conjugated dienes, as shown in Scheme 4. The butadiene, 1,3-pentadiene, and 1,4-diphenylbutadiene complexes of  $\text{Cp}^*\text{TiX}$  exhibit a unique prone (endo) conformation (**13**), while the isoprene, 2,3-dimethylbutadiene, and 2,3-diphenylbutadiene complexes prefer the supine (exo) conformation (**14**). Reduction of  $\text{Cp}^*\text{TiX}(\text{diene})$  with  $\text{RMgX}$  or  $\text{Mg}$  gives a low-valent species, which catalyzes a highly selective (>99%) tail-to-head linear dimerization of isoprene and 2,3-dimethylbutadiene.<sup>54,55</sup>

Scheme 4

Addition of  $[\text{o}-(\text{CH}_2)_2\text{C}_6\text{H}_4]\text{Mg}(\text{THF})_2$  to  $\text{Cp}^*\text{TiCl}_3$  in toluene gives the expected *o*-xylylene complex  $\text{Cp}^*\text{TiCl}[\text{o}-(\text{CH}_2)_2\text{C}_6\text{H}_4]$ . However, reaction of  $[\text{o}-(\text{CH}_2)_2\text{C}_6\text{H}_4]\text{Mg}(\text{THF})_2$  with  $\text{Cp}^*\text{TiCl}_3$  in THF leads to the dinuclear bis(diene)titanium complex (**15**), in which two  $\text{Cp}^*\text{TiCl}$  fragments bond to *o*-xylylene through its exo- and endocyclic diene systems via  $\sigma^2$  and  $\eta^4$  bonding modes, respectively.<sup>56</sup>

Diene–cyclopentadienyl titanium halide complexes react readily with unsaturated organic molecules. For example, reaction of  $\text{Cp}^*\text{TiCl}(\eta^4\text{-CH}_2=\text{CH}(\text{Me})\text{CH}(\text{Me})=\text{CH}_2)$  with symmetrical alkynes  $\text{RC}\equiv\text{CR}$  ( $\text{R} = \text{Me}, \text{Ph}$ ) leads to reductive coupling (see *Reductive Coupling*) of the alkynes to give metallacyclo-2,4-pentadiene products  $\text{Cp}^*\text{Ti}(\text{C}(\text{Ph})=\text{C}(\text{Ph})\text{C}(\text{Ph})=\text{C}(\text{Ph}))\text{Cl}$  and the dinuclear metallacycle  $[\text{Cp}^*\text{TiCl}]_2(\text{C}_4\text{Me}_4)$  (**16**).<sup>57</sup> In an analogous manner, treatment of  $\text{Cp}^*\text{Ti}(\text{CH}_2=\text{C}(\text{Me})\text{C}(\text{Me})=\text{CH}_2)\text{Cl}$  with 2,6-xylyl isocyanide at  $-30^\circ\text{C}$  gives the dimeric complex  $(\text{Cp}^*\text{TiCl})_2[\mu\text{-N}_2\text{C}_2(2,6\text{-xylyl})_2]$  (**17**) in 47% yield. Lesser amounts of (**18**) and (**19**) are also formed in this reaction, as shown in Scheme 5.<sup>58</sup>

The cyclooctatetraene–diene complex  $[(\eta^4\text{-C}_4\text{H}_6)\text{cot}]\text{Ti}$  has been reported and has been shown by  $^1\text{H}$  NMR spectra to adopt an *s-cis*- $\eta^4$ -butadiene conformation.<sup>59</sup>

Reduction of  $\text{TiCl}_4(\text{THF})_2$  with 2 equivalents of  $\text{Mg}$  in the presence of 2 equivalents of a sterically demanding 1-aza-1,3-diene,  $\text{ArN}=\text{CHC}(\text{CH}_3)=\text{CAr}$  ( $\text{Ar} = 1,5$  (*i*-pr) $_2\text{C}_6\text{H}_3$ ), gives the homoleptic early transition metal 1-aza-1,3-diene complex,  $\text{Ti}(\text{1-aza-1,3-diene})_2$ . X-ray diffraction analysis of this complex shows Ti–N distances of 1.949(2) and 1.939(2) Å and Ti–C distances of 2.317(3) and 2.132(3) Å. The subsequent addition of  $\text{MeLi}$  and elimination of methane

Scheme 5

results in the formation of a novel metallacyclic titanium alkylidene complex, which affords the opportunity to compare of Ti–C  $\sigma$ -bond (2.163(3) Å) and Ti=C-bond (1.978(3) Å) distances within the same molecule.<sup>60</sup>

Reaction of  $\text{TiCl}_4\text{THF}_2$  with  $\text{Na}_2[\text{MePhN}=\text{C}=\text{C}=\text{NPhMe}]$  ( $\text{Ph} = \text{C}_6\text{H}_5$ , 4-MeC<sub>6</sub>H<sub>4</sub> and 2-MeC<sub>6</sub>H<sub>4</sub>) or by reduction of  $\text{TiCl}_4\text{THF}_2$  with Mg in presence of 2 equivalent of  $\text{MePhN}=\text{C}=\text{C}=\text{NPhMe}$  give the corresponding homoleptic 1,4-diaza-1,3-diene complexes. The endiamide complexes are thermally stable and very sensitive to oxygen and water. An X-ray crystal structure reveals the Ti atom in these complexes is in a strongly distorted tetrahedral environment. The two 5-membered metallacyclic rings are folded along the  $N, N'$  axis. Temperature-dependent <sup>1</sup>H NMR spectra indicate a rapid intramolecular inversion of this nonplanar ring system in solution even at room temperature. Reduction of  $\text{TiCl}_4\text{THF}_2$  with Mg in presence of excess DAD [ $\text{PhRN}=\text{C}=\text{C}=\text{NRPh}$  (DAD; R = Ph, 4-MeC<sub>6</sub>H<sub>4</sub>, 4-MeOC<sub>6</sub>H<sub>4</sub>)] gives the blue-violet complexes  $(\text{DAD})_3\text{Ti}$ .<sup>61</sup>

an unusual staggered configuration with a nitrogen center–titanium center–nitrogen’ torsional angle of 140.1°.<sup>64,65</sup>

Since bis-arene titanium complexes were initially prepared by metal-atom chemistry, ‘conventional’ chemical synthesis of bis-arene titanium complexes has been developed. Treatment of  $\text{TiCl}_4(\text{THF})_2$  with  $\text{K}(\text{Ph}-\text{Ph})_2$  and  $\text{K}(4,4'\text{-}t\text{-Bu}_2\text{Ph}-\text{Ph})_2$  gives  $\text{K}[\text{Ti}(\eta^6\text{-Ph}-\text{Ph})_2]$  (equation 14) and  $\text{K}[\text{Ti}(\eta^6\text{-}4,4'\text{-}t\text{-Bu}_2\text{Ph}-\text{Ph})_2]$ , respectively, which are isolated as the corresponding  $\text{K}([2.2.2]\text{cryptand})$  or  $\text{K}(15\text{-crown-}5)_2$  bis(arene)titanates. Oxidation of these complexes with  $\text{I}_2$  gives the corresponding bis-arene complexes (equation 15).<sup>66</sup> Ultrasound-mediated reduction of  $\text{TiCl}_4(\text{THF})_2$  or  $\text{TiCl}_3(\text{THF})_3$  with  $\text{K}[\text{BEt}_3\text{H}]$  in benzene, toluene, *p*-xylene, or mesitylene gives the corresponding bis( $\eta^6$ -arene)titanium complexes directly (equation 16).<sup>67</sup>

## 8 ARENE COMPLEXES

### 8.1 Bis-arene Complexes

Bis-arene titanium complexes (*see Arene Complexes*) such as  $(\eta^6\text{-C}_6\text{H}_6)_2\text{Ti}$  were first prepared by Green and coworkers by the reaction of titanium atoms with arenes on a liquid nitrogen cooled surface (equation 13).<sup>62</sup> A wide range of aromatic ligands have been incorporated in bis-arene titanium complexes by metal vapor synthesis, including highly sterically hindered arenes ( $(\eta^6\text{-}t\text{-Bu}_3\text{C}_6\text{H}_3)_2\text{Ti}$ ) and heterocyclic arenes ( $(\eta^6\text{-}2,6\text{-Me}_2\text{C}_5\text{H}_3\text{N})_2\text{Ti}$ ).<sup>63</sup> Bis-arene titanium complexes are diamagnetic and exhibit sandwich structures (*see Sandwich Compound*) with essentially mutually parallel eclipsed planar arene ligands. However,  $(\eta^6\text{-}2,6\text{-Me}_2\text{C}_5\text{H}_3\text{N})_2\text{Ti}$  exhibits

### 8.2 Monoarene complexes

Treatment of  $[(\text{Me}_2\text{PCH}_2)_3\text{Si-}t\text{-Bu}]\text{TiCl}_3(\text{THF})$  with sodium naphthalenide in THF gives  $(\eta^6\text{-C}_{10}\text{H}_8)\text{Ti}[(\text{Me}_2\text{PCH}_2)_3\text{Si-}t\text{-Bu}]$  in 40% yield.<sup>68</sup>

Diamagnetic titanium(II) arene complexes  $(\eta^6\text{-C}_6\text{H}_6)\text{Ti}[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) (**20**) have been prepared by the reduction of  $\text{TiX}_4$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) with Al in the presence of  $\text{AlCl}_3$  in  $\text{C}_6\text{H}_6$  (equation 17). The arene ligands in these complexes are  $\eta^6$  coordinated to the titanium, which exhibits square pyramidal coordination with four halides of

two  $\text{AlX}_4$  anions forming the basal square plane.

Treatment of  $(\eta^6\text{-arene})\text{Ti}[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{X} = \text{Br}, \text{I}$ ) complexes with CO at low temperature gives the corresponding dicarbonyl derivatives  $[(\eta^6\text{-arene})\text{Ti}(\text{CO})_2[(\mu\text{-X})(\text{AlX}_2)]]\text{AlX}_4$  (equation 18). Treatment of  $(\eta^6\text{-arene})\text{Ti}(\text{CO})_2[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{X} = \text{Cl}, \text{Br}$ ) with  $\text{CpTiI}$  and 1 atm of CO at room temperature leads to the loss of the arene ligand and gives  $\text{Cp}_2\text{Ti}(\text{CO})_2$  in good yields (equation 19).<sup>69</sup>

Reaction of  $\text{Ti}(\eta^6\text{-MePh})[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{X} = \text{Cl}, \text{Br}$ ) with alkynes  $\text{RC}\equiv\text{CR}$  ( $\text{R} = \text{Me}, \text{Ph}$ ) gives tetramethyl- and tetraphenylcyclobutadiene complexes,  $\text{Ti}(\eta^4\text{-C}_4\text{R}_4)[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{R} = \text{Ph}, \text{X} = \text{Cl}, \text{Br}; \text{R} = \text{Me}, \text{X} = \text{Br}$ ), in good yield. The titanium atom in  $\text{Ti}(\eta^4\text{-C}_4\text{Ph}_4)[(\mu\text{-Br})_2(\text{AlBr}_2)]_2$  is found to have approximately square pyramidal coordination, with the apical position occupied by the symmetrically bonded tetraphenylcyclobutadiene ring with four bromines of two  $\text{AlBr}_4$  anions forming the base of the pyramid. Treatment of  $\text{Ti}(\eta^4\text{-C}_4\text{Ph}_4)[(\mu\text{-Br})_2(\text{AlBr}_2)]_2$  with  $\text{CpTiI}$  and  $\text{K}_2\text{cot}$  forms  $\text{Cp}_2\text{Ti}[\text{C}(\text{Ph})=\text{C}(\text{Ph})\text{C}(\text{Ph})=\text{C}(\text{Ph})]$  and  $(\text{cot})\text{Ti}(\eta^4\text{-C}_4\text{Ph}_4)$ , respectively, as shown in Scheme 6.  $\text{Ti}(\eta^6\text{-MePh})[(\mu\text{-X})_2(\text{AlX}_2)]_2$  ( $\text{X} = \text{Cl}, \text{Br}$ ) has been shown to cyclotrimerize (see *Cyclodimerization & -trimerization Reactions*) alkynes at  $89^\circ\text{C}$ .<sup>70</sup>

Reduction of  $\text{TiCl}_4(\text{dmpe})$  or  $\text{Cp}^*\text{TiCl}_3$  with K or Na anthracene in THF gave  $[\text{Ti}(\eta^6\text{-C}_{14}\text{H}_{10})(\eta^4\text{-C}_{14}\text{H}_{10})(\text{dmpe})]$  and  $[\text{Cp}^*\text{Ti}(\eta^4\text{-C}_{14}\text{H}_{10})(\eta^2\text{-C}_{14}\text{H}_{10})]^-$ , respectively. Treatment of  $[\text{Ti}(\eta^6\text{-C}_{14}\text{H}_{10})(\eta^4\text{-C}_{14}\text{H}_{10})(\text{dmpe})]$  and  $[\text{Cp}^*\text{Ti}(\eta^4\text{-C}_{14}\text{H}_{10})(\eta^2\text{-C}_{14}\text{H}_{10})]^-$  with carbon monoxide in THF at  $-55^\circ\text{C}$  led to loss of the anthracene ligands to give  $\text{Ti}(\text{CO})_3(\text{dmpe})_2$  and  $\text{Cp}^*[\text{Ti}(\text{CO})_4]^-$  in 57% and 62% yields, respectively.<sup>71</sup>

A small number of titanium complexes with heterocyclic ligands have been prepared. Reaction of  $\text{TiCl}_4(\text{THF})_2$

Scheme 6

with 2,3,4,5-tetramethyl-1-trimethylstannyl phosphole in  $\text{CH}_2\text{Cl}_2/\text{pentane}$  followed by reduction with Mg in the presence of CO gives  $(\eta^5\text{-2,3,4,5-C}_4\text{Me}_4\text{P})\text{Ti}(\text{CO})_2$  in 39% yield.<sup>72</sup> Reaction of  $\text{TiCl}_4$  with  $\text{Li}(\text{C}_5\text{H}_5\text{BMe})$ , 2-( $\text{Me}_3\text{Si}$ ) $\text{C}_5\text{H}_5\text{BMe}$ , or 2-( $\text{Me}_3\text{Sn}$ ) $\text{C}_5\text{H}_5\text{BMe}$  gives  $\text{TiCl}_3(\eta^6\text{-C}_5\text{H}_5\text{BMe})$  in excellent yield.  $\text{CpTiCl}_2(\eta^6\text{-C}_5\text{H}_5\text{BMe})$  was prepared in an analogous manner starting with  $\text{CpTiCl}_3$  in place of  $\text{TiCl}_4$ .<sup>73</sup> The addition of potassium-pyrrole to  $[\text{K}(15\text{-crown-5})_2][\text{Ti}(\text{CO})_4(\eta^3\text{-BH}_4)]$  gives  $[\text{K}(15\text{-crown-5})_2][(\eta^5\text{-C}_4\text{H}_4\text{N})\text{Ti}(\text{CO})_4]$ .<sup>25</sup>

## 9 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(IV)

The vast majority of the organometallic chemistry of titanium is based upon complexes that incorporate one or two cyclopentadienyl or substituted cyclopentadienyl groups as ancillary ligands. Cyclopentadienyl (see *Cyclopentadienyl*) and substituted cyclopentadienyl ligands are ubiquitous in the organometallic chemistry of titanium. Bis(cyclopentadienyl)- and substituted bis(cyclopentadienyl)titanium dichloride complexes have been prepared by treatment of  $\text{TiCl}_4$ , or  $\text{TiCl}_3$  followed by an oxidative work-up, with a wide range of cyclopentadienyl and substituted cyclopentadienyl salts of several metals, including  $\text{Li}^+$ ,  $\text{Na}^+$  (equation 20),  $\text{MgX}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Tl}^+$ , and  $\text{Pb}^{2+}$ .  $\text{Bu}_2\text{TiCl}_2$ , generated in hydrocarbon media at  $-78^\circ\text{C}$  by treating  $\text{TiCl}_4$  with 2 equivalent of  $\text{BuLi}$ , functions as a strong base toward cyclopentadiene, substituted cyclopentadiene, and indene giving  $\text{Cp}_2\text{TiCl}_2$  derivatives in high yield (equation 21).<sup>74</sup> Treatment of  $\text{Ti}(\text{NMe}_2)$  and  $\text{Ti}(\text{NEt}_2)_4$  the cyclopentadiene derivatives to give metallocenes (see *Metallocene Complexes*) (equation 22).<sup>75</sup> Modifications of this reaction have recently been widely used to prepare substituted Cp complexes including *ansa*-metallocenes and constrained geometry complexes.

$\text{CpTiCl}_3$  is conveniently prepared by treatment of  $\text{TiCl}_4$  with  $\text{CpSiMe}_3$  (equation 23).<sup>76</sup> The synthesis and reactivity bis(cyclopentadienyl)titanium through the mid- 90s has been extensively reviewed by Bechaus up.<sup>77</sup> The synthesis of chiral titanocene derivatives has been reviewed by Halterman.<sup>78</sup>

$\text{Cp}_2^*\text{TiCl}_2$  is readily prepared by reaction of 2 equivalent of  $\text{Na}[\text{C}_5\text{Me}_5]$  with  $\text{TiCl}_3$ , followed by oxidative work-up (equation 24).<sup>79</sup> The mono-ring complexes  $\text{Cp}^*\text{TiX}_3$  ( $\text{X} = \text{Cl}, \text{Br}$ ) are best prepared, in nearly quantitative yield, by the treatment of  $\text{TiX}_4$  with  $(\text{C}_5\text{Me}_5)\text{SiMe}_3$  (equation 25).<sup>80</sup>

Treatment of  $\text{Cp}_2\text{TiCl}_2$  with 1 equivalent of Grignard reagent (see *Grignard Reagents*) provides a convenient route for the preparation of the mono( $\sigma$ -hydrocarbyl) complexes,  $\text{Cp}_2\text{TiRCl}$  ( $\text{R} = \text{Me}, \text{Et}, n\text{-Pr}, n\text{-Bu}, i\text{-Bu}, n\text{-C}_5\text{H}_{11}, \text{CH}_2\text{Bu-}t, \text{CH}_2\text{Ph}, \text{CH}_2\text{SiMe}_3, \text{ and Ph}$ ) (equation 26). Treatment of  $\text{Cp}_2\text{TiCl}_2$  with 2 equivalent of  $\text{MeLi}$  or  $\text{MeMgX}$  leads to  $\text{Cp}_2\text{TiMe}_2$  in good yield (equation 27).  $\text{Cp}_2\text{TiMe}_2$  undergoes decomposition at room temperature rapidly in light and more slowly in the dark. Similar routes have been used to prepare other bis-alkyl and -aryl complexes; however, the stability of these complexes varies widely.  $\text{Cp}_2\text{Ti}(\text{Et})_2$  decomposes below  $40^\circ\text{C}$ , while  $\text{Cp}_2\text{Ti}(n\text{-Bu})_2$  decomposes above  $-50^\circ\text{C}$  in solution.  $\text{Cp}_2\text{Ti}(\text{R})_2$  compounds not containing  $\beta$ -hydrogens exhibit considerably greater stability. Thus,  $\text{Cp}_2\text{Ti}(\text{CH}_2\text{SiMe}_3)_2$  and  $\text{Cp}_2\text{TiPh}_2$  exhibit good stability at room temperature; however, they undergo thermolysis in refluxing benzene, which has been well studied. Treatment of  $\text{Cp}_2\text{TiCl}_2$  with 2 equivalent of the more sterically demanding  $\text{LiCHPh}_2$  or  $\text{LiCH}(\text{SiMe}_3)_2$  leads to reduction of the titanium center to give  $\text{Cp}_2\text{TiCHPh}_2$  (equation 28) and  $\text{Cp}_2\text{TiCH}(\text{SiMe}_3)_2$ , respectively, while treatment of  $\text{Cp}_2\text{TiCl}_2$  with 1 equivalent of  $\text{LiCH}(\text{SiMe}_3)_2$  gives  $\text{Cp}_2\text{TiCl}$  (equation 29).<sup>81</sup>

In contrast to the preparation of  $\text{Cp}_2\text{TiClR}$  (see above), treatment of  $\text{Cp}_2^*\text{TiCl}_2$  with 1 equivalent of  $\text{Me}, \text{Et},$  or  $\text{Pr}$ , Grignard or lithium reagents gives a mixture of  $\text{Ti}^{\text{III}}$  and  $\text{Ti}^{\text{IV}}$  complexes.<sup>42</sup>

The replacement of the cyclopentadienyl group with the strongly electron-donating and sterically more demanding pentamethylcyclopentadienyl group has been found to impart enhanced solubility and increased kinetic stability to many transition metal complexes. This enhanced stability is typified by the difference in stability of  $\text{Cp}_2\text{TiMe}_2$  and  $\text{Cp}_2^*\text{TiMe}_2$ . While  $\text{Cp}_2\text{TiMe}_2$  undergoes decomposition at room temperature rapidly in light and more slowly in the dark,  $\text{Cp}_2^*\text{TiMe}_2$  is sufficiently stable to be stored at room temperature for an extended time.  $\text{Cp}_2\text{TiMe}_2$  is thought to decompose via  $\alpha$ -hydrogen elimination to give products which have not been fully characterized. Bercaw has established that upon heating to  $110^\circ\text{C}$ ,  $\text{Cp}_2^*\text{TiMe}_2$  undergoes  $\alpha$ -hydrogen abstraction or  $\alpha$ -hydrogen elimination (see  *$\alpha$ -Elimination*) followed by loss of methane to give the methylidene intermediate (21) (equation 30). This intermediate titanium methylidene complex undergoes hydrogen migration from a ring methyl group to the methylidene to give the turquoise fulvene complex  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{TiMe}$  (22).<sup>82</sup> Thermolysis of  $(\eta^5\text{-C}_5\text{Me}_4\text{H})_2\text{TiMe}_2$  at  $130^\circ\text{C}$  gives the analogous fulvene complex  $(\eta^5\text{-C}_5\text{Me}_4\text{H})(\eta^6\text{-C}_5\text{Me}_3\text{HCH}_2)\text{TiMe}$ .<sup>83</sup>

## 9.1 Bulky Ligands

Considerable work in recent years has been devoted to the synthesis of ring-substituted derivatives of bis( $\eta^5$ -cyclopentadienyl)titanium dihalides. The ring orientation in

the bis( $\eta^5$ -alkylcyclopentadienyl)titanium dihalide derivatives that have been structurally characterized, to date, can be divided into two categories, which are illustrated schematically by (23) and (24) (Table 1).

Several groups have investigated the incorporation of 1,3-di-*t*-butylcyclopentadienyl ligands in mono- and bis-cyclopentadienyltitanium complexes. The sterically congested compounds ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>TiCl<sub>2</sub> and ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)TiCl<sub>3</sub> are prepared in good yields by treating TiCl<sub>4</sub> or TiCl<sub>3</sub> with 2 or 1 equivalent of [1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>]*i*Li, respectively.<sup>85,86</sup>

Reduction of ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>TiCl<sub>2</sub> with K metal in pentane gives the paramagnetic titanium(III) complex ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>TiCl in high yield.<sup>87</sup> Treatment of ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>TiCl<sub>2</sub> with LiBH<sub>4</sub> in Et<sub>2</sub>O leads to reduction of the titanium center to give ( $\eta^5$ -1,3-*t*-Bu<sub>2</sub>C<sub>5</sub>H<sub>3</sub>)<sub>2</sub>TiBH<sub>4</sub>. The Ti···B bond length is found to be 2.41 Å and the H–Ti–H bond angle is 58.2°.<sup>88</sup>

Bis- and tris(trimethylsilyl)cyclopentadienyl derivatives, Ti[ $\eta^5$ -1,3-(SiMe<sub>3</sub>)<sub>2</sub>C<sub>5</sub>H<sub>3</sub>]<sub>2</sub>TiCl<sub>2</sub> and [ $\eta^5$ -1,2,4-(Me<sub>3</sub>Si)<sub>3</sub>C<sub>5</sub>H<sub>2</sub>]<sub>2</sub>TiCl<sub>3</sub>, have been prepared in good yield by treating TiCl<sub>3</sub> with Li[1,3-(SiMe<sub>3</sub>)<sub>2</sub>C<sub>5</sub>H<sub>3</sub>] or Li[1,2,4-(Me<sub>3</sub>Si)<sub>3</sub>C<sub>5</sub>H<sub>2</sub>], respectively, followed by oxidative work-up.<sup>89,90</sup>

Reaction of TiCl<sub>3</sub>(THF)<sub>3</sub> with 1 equivalent of the sterically demanding Li[*i*-PrC<sub>5</sub>Me<sub>4</sub>] in THF, followed by oxidation with HCl, affords ( $\eta^5$ -*i*-PrC<sub>5</sub>Me<sub>4</sub>)TiCl<sub>3</sub> in 66% yield. Treatment of ( $\eta^5$ -*i*-PrC<sub>5</sub>Me<sub>4</sub>)TiCl<sub>3</sub> with CpTiI in refluxing benzene forms (Cp)( $\eta^5$ -*i*-PrC<sub>5</sub>Me<sub>4</sub>)TiCl<sub>2</sub> in 95% yield. The highly sterically congested complex ( $\eta^5$ -*i*-PrC<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub> is prepared in 93% yield by reaction of TiCl<sub>3</sub>(THF)<sub>3</sub> with 2 equivalent of Li[*i*-PrC<sub>5</sub>Me<sub>4</sub>] in THF, followed by oxidation with HCl. The ring centroid–titanium–ring centroid angle of 137.4(1)° of ( $\eta^5$ -*i*-PrC<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub> is identical, within experimental error, to

that found in Cp<sub>2</sub>\*TiCl<sub>2</sub>; however, the Cl–Ti–Cl bond angle of 88.81° is unusually acute (see Table 1).<sup>84</sup>

Treatment of TiCl<sub>3</sub> with Li(Ph<sub>4</sub>C<sub>5</sub>H) or K(Ph<sub>4</sub>C<sub>5</sub>H) gives (Ph<sub>4</sub>C<sub>5</sub>H)<sub>2</sub>TiCl, which, upon treatment with HCl/THF or AgCl, affords the highly sterically hindered complex (Ph<sub>4</sub>C<sub>5</sub>H)<sub>2</sub>TiCl<sub>2</sub>.<sup>91</sup> In contrast to the less sterically hindered [Cp<sub>2</sub>TiCl]<sub>2</sub>, (Ph<sub>4</sub>C<sub>5</sub>H)<sub>2</sub>TiCl crystallizes as well-separated monomeric units with the tetraphenylcyclopentadienyl rings staggered, with a ring centroid–metal–ring centroid angle of 136.4°, and a short Ti–Cl bond length of 2.312(2) Å. Solution EPR (see *Electron Paramagnetic Resonance*) studies show evidence for free (C<sub>5</sub>Ph<sub>4</sub>H)<sub>2</sub>TiCl (*g* = 1.957) and a THF adduct (*g* = 1.979). Reduction of a THF solution of (Ph<sub>4</sub>C<sub>5</sub>H)<sub>2</sub>TiCl with sodium naphthalenide under argon and CO yields a species with IR absorptions at 1966 and 1892 cm<sup>−1</sup>, which suggests the formation of (C<sub>5</sub>Ph<sub>4</sub>H)<sub>2</sub>Ti(CO)<sub>2</sub>.<sup>92</sup>

Reaction of CpTiCl<sub>3</sub> with K(C<sub>5</sub>Ph<sub>5</sub>) or K(C<sub>5</sub>Ph<sub>4</sub>H) in THF gives Cp( $\eta^5$ -Ph<sub>5</sub>C<sub>5</sub>)TiCl<sub>2</sub> and Cp( $\eta^5$ -Ph<sub>4</sub>C<sub>5</sub>H)TiCl<sub>2</sub>, respectively. The Ti–C bond lengths for the C<sub>5</sub>Ph<sub>5</sub> group in Cp( $\eta^5$ -Ph<sub>5</sub>C<sub>5</sub>)TiCl<sub>2</sub> are found to be considerably longer than those for the C<sub>5</sub>H<sub>5</sub> group; average bond lengths are 2.53(3) and 2.39(4) Å, respectively.<sup>93</sup>

## 9.2 Functionalized Ligands

Cyclopentadienyl ligands incorporating potentially chemically reactive functional groups have also been used in the preparation of bis(cyclopentadienyl)titanium dihalides. For example, reaction of (methoxycarbonylcyclopentadienyl)thallium with CpTiCl<sub>3</sub> or TiCl<sub>4</sub> gives Cp( $\eta^5$ -MeOC(O)C<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub> and ( $\eta^5$ -MeOC(O)C<sub>5</sub>H<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub>, respectively, in good yield. Reductive carbonylation of these complexes affords Cp( $\eta^5$ -MeOC(O)C<sub>5</sub>H<sub>4</sub>)Ti(CO)<sub>2</sub> and ( $\eta^5$ -MeOC(O)C<sub>5</sub>H<sub>4</sub>)<sub>2</sub>Ti(CO)<sub>2</sub>, respectively, in good yield.<sup>94</sup>

Treatment of TiCl<sub>4</sub> with 2 equivalent of Li[ClC<sub>5</sub>H<sub>4</sub>] or Ti[ClC<sub>5</sub>H<sub>4</sub>] forms ( $\eta^5$ -ClC<sub>5</sub>H<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub>, while treatment of CpTiCl<sub>3</sub> with Ti[ClC<sub>5</sub>H<sub>4</sub>] gives Cp( $\eta^5$ -ClC<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub> in good yields. Reductive carbonylation of ( $\eta^5$ -ClC<sub>5</sub>H<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub> and Cp( $\eta^5$ -ClC<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub> leads to the corresponding dicarbonyl derivatives.<sup>94,95</sup>

Several groups have prepared titanium-based metallocenes incorporating phosphine-substituted cyclopentadienyl ligands as the first step in the synthesis of new bimetallic complexes. Treatment of CpTiCl<sub>3</sub> with Ti(Ph<sub>2</sub>PC<sub>5</sub>H<sub>4</sub>) affords Cp( $\eta^5$ -(Ph<sub>2</sub>P)C<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub> in 95% yield. Reductive carbonylation of Cp( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub> gives Cp( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>H<sub>4</sub>)Ti(CO)<sub>2</sub>. Both of these phosphine-substituted titanocene complexes react with Cp(CO)<sub>2</sub>(THF)Mn to give the corresponding bimetallic complexes CpMn(CO)<sub>2</sub>{(Cp)( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>H<sub>4</sub>)TiCl<sub>2</sub>} and CpMn(CO)<sub>2</sub>{Cp( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>H<sub>4</sub>)Ti(CO)<sub>2</sub>} in good yield.<sup>96</sup>

Reaction of Li[Ph<sub>2</sub>PC<sub>5</sub>Me<sub>4</sub>] with CpTiCl<sub>3</sub> and TiCl<sub>3</sub> followed by treatment with CCl<sub>4</sub> leads to the formation of Cp( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>Me<sub>4</sub>)TiCl<sub>2</sub> and ( $\eta^5$ -Ph<sub>2</sub>PC<sub>5</sub>Me<sub>4</sub>)<sub>2</sub>TiCl<sub>2</sub>,

**Table 1** Structural Parameters for RCp<sub>2</sub>TiCl<sub>2</sub> Complexes<sup>84</sup>

|                                                                                              | Structure type | Cp–M–Cp (°) | Cl–M–Cl (°) |
|----------------------------------------------------------------------------------------------|----------------|-------------|-------------|

respectively, in good yield.<sup>97</sup> In an analogous manner, reaction of  $\text{Ti}[\text{Ph}_2\text{PC}_5\text{Me}_4]$  and  $\text{Ti}[\text{Me}_2\text{PC}_5\text{Me}_4]$  with  $\text{Cp}^*\text{TiCl}_3$  forms  $[\eta^5\text{-Ph}_2\text{PC}_5\text{Me}_4]_2\text{TiCl}_2$  and  $[\eta^5\text{-Me}_2\text{PC}_5\text{Me}_4]_2\text{TiCl}_2$ , respectively, in good yield.<sup>98</sup> The metalloligand  $[\eta^5\text{-(Ph}_2\text{P)C}_5\text{Me}_4]_2\text{TiCl}_2$  reacts readily with  $\text{Mo(CO)}_4\text{cod}$ ,  $\text{Mo(CO)}_5\text{THF}$ , and  $\text{Mo(CO)}_6$  to give in each case  $[\text{cyclic}][(\eta^5\text{-Ph}_2\text{PC}_5\text{Me}_4)_2\text{TiCl}_2]\text{Mo(CO)}_4$  as the sole product. The long Mo–Ti distance of 5.194(1) Å in this complex rules out any metal–metal interaction.<sup>96</sup>

The reaction of  $(\text{CpTiCl}_2)_n$  and  $\text{Cp}^*\text{TiCl}_2(\text{THF})$  with  $\text{Li(C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)$  gives  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{CpTiCl}$  and  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{TiCl}$ , respectively, which are oxidized by  $\text{PbCl}_2$  to give  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{CpTiCl}_2$  and  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{TiCl}_2$ , respectively. The nitrogen of the  $\text{NMe}_2$  group in  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{CpTiCl}$  was found to bond with the Ti (Ti–N, 2.437(3) Å), while the  $\text{NMe}_2$  group in  $(\text{C}_5\text{Me}_4\text{CH}_2\text{CH}_2\text{NMe}_2)\text{Cp}^*\text{TiCl}_2$  was found not to be coordinated to the titanium in the solid state by single-crystal X-ray diffraction.<sup>48</sup>

Chlorosilyl-cyclopentadienyl titanium complexes have been prepared, as starting materials allowing further modification. Treatment of  $\text{MCl}_4$  with two equivalents of  $\text{C}_5\text{H}_5(\text{SiClMe}_2)$  in toluene under reflux and in the presence of two equivalents of  $\text{NEt}_3$  gives  $(\eta^5\text{-C}_5\text{H}_4\text{SiClMe}_2)_2\text{TiCl}_2$ .<sup>99</sup>  $[\text{Ti}(\eta^5\text{-C}_5\text{Me}_4\text{SiMeCl}_2)\text{Cl}_3]$  and  $[\text{Ti}(\eta^5\text{-C}_5\text{Me}_4\text{SiMeHCl})\text{Cl}_3]$ , are prepared by the treatment of  $\text{TiCl}_4$  with the trimethylsilyl derivatives of the corresponding cyclopentadienes. Methylation of these complexes with  $\text{MeMgCl}$  gives the corresponding Me complexes  $[\text{Ti}(\eta^5\text{-C}_5\text{Me}_4\text{SiMe}_2\text{R})\text{XMe}_2]$  (R = H, Cl; Me; R = X = Me).<sup>100</sup>

$\text{K}[\text{C}_5\text{Me}_4\text{-P-}t\text{-Bu(NEt}_2)]$  and  $\text{K}[t\text{-BuC}_5\text{H}_3\text{-P-}t\text{-Bu(NEt}_2)]$  are efficiently transmetalated by  $\text{Me}_3\text{SnCl}$ , subsequent reaction with  $\text{TiCl}_4(\text{L})_2$  (L = THF, tetrahydrothiophene,  $\text{Me}_3\text{P}$ ) gives the half-sandwich complexes (*see Half-sandwich Complexes*)  $[\text{Me}_4\text{Cp-P-}t\text{-Bu(NEt}_2)]\text{TiCl}_3$  and  $[t\text{-BuC}_5\text{H}_3\text{-P-}t\text{-Bu(NEt}_2)]\text{TiCl}_3$ , respectively in moderate yields. Treatment of  $[t\text{-BuC}_5\text{H}_3\text{-P-}t\text{-Bu(Cl)}]$  with  $\text{TiCl}_4$  in the presence of  $\text{Et}_3\text{N}$  at low temperature gives the half-sandwich complex  $[t\text{-BuC}_5\text{H}_3\text{-P-}t\text{-Bu(Cl)}]\text{TiCl}_3$  quantitative yield.<sup>101</sup>

### 9.3 Annulated Cyclopentadienyl Ligands

Considerable effort has been directed to the stereoselective synthesis of annulated cyclopentadienyl complexes of the group 4 transition metals.  $C_1$  asymmetric and  $C_2$  symmetric annulated cyclopentadienyl ligands have been used to prepare chiral organotitanium complexes, which are now being actively studied as catalysts for asymmetric synthesis and olefin polymerization (*see Asymmetric Synthesis by Homogeneous Catalysis*).

Halterman and Vollhardt<sup>102</sup> and Paquette and coworkers<sup>103</sup> have prepared bis(annulated cyclopentadienyl)titanium complexes, and have separated (25) and (26) when starting from the chiral natural product camphor. They have shown that

use of complex (25) as a catalyst precursor for asymmetric hydrogenation of 2-phenylbutene forms 2-phenylbutane quantitatively at up to 34% *ee*.

The  $C_2$  symmetric chiral cyclopentadienes (+)-(1*R*, 7*R*, 8*R*, 10*R*)-8,10-diisopropyltricyclo[5.2.2.0<sup>2,6</sup>]undeca-2,5-diene ( $\text{Me}_2\text{-BCO-CpH}$ ) and (–)-(1*S*, 7*S*, 8*R*, 10*R*)-8,10-dimethyltricyclo[5.2.2.0<sup>2,6</sup>]undeca-2,5-diene ( $\text{BCO-CpH}$ ) have been metalated and treated with  $\text{TiCl}_3$ , followed by oxidative work-up, to give enantiomerically pure  $(\text{Me}_2\text{-BCO-Cp})_2\text{TiCl}_2$  and  $(\text{BCO-Cp})_2\text{TiCl}_2$  in 45 and 55% yield, respectively (equations 31 and 32).<sup>104</sup>

Paquette and coworkers have extensively studied the complexation of  $C_1$  symmetric annulated cyclopentadienides with  $\text{TiCl}_3$ ,  $\text{TiCl}_4$ ,  $\text{CpTiCl}_3$ , and  $\text{Cp}^*\text{TiCl}_3$  to give the corresponding complexes. Reaction of lithium isodicyclopentadienide ( $\text{isodiCpLi}$ ) with  $\text{CpTiCl}_3$ ,  $\text{MeCpTiCl}_3$ , or  $\text{Cp}^*\text{TiCl}_3$  proceeds under conditions which are kinetically controlled and take place with complete bifacial stereoselectivity depending upon temperature (with endo complexation occurring at  $-78^\circ\text{C}$  and exo complexation occurring at room temperature and above).<sup>105</sup> For example, treatment of  $\text{CpTiCl}_3$  with  $\text{isodiCpLi}$  at  $-78^\circ\text{C}$  gives (27), while the same reaction at room temperature gives (28). Paquette and coworkers have prepared each of the three possible diisodicyclopentadienyltitanium dichlorides with a high degree of selectivity. The pronounced influence

of reaction temperature on stereoselectivity is further demonstrated by reacting  $\text{TiCl}_3$  with the isodiCpLi at 25 °C, followed by oxidative work-up, to obtain the *exo,exo* isomer, or reacting at -64 °C for the *endo,endo* isomer. In the *exo,exo* isomer, the cyclopentadienyl rings are almost eclipsed and the norbornane substituents on the rings are oriented away from each other. The Cl-Ti-Cl and ring centroid-Ti-ring centroid angles of 92.94 and 131.0°, respectively, are within the normal range for  $\text{Cp}_2\text{TiCl}_2$  complexes (see Table 1). *Exo*-isodiCpTiCl<sub>3</sub> was synthesized specifically by treatment of  $\text{TiCl}_4$  with isodiCpSiMe<sub>3</sub>. Reaction of *exo*-isodiCpTiCl<sub>3</sub> with isodiCpLi at -78 °C leads to the *endo,exo* isomer selectively.<sup>106,107</sup> The three diastereomeric (isodiCp)<sub>2</sub>TiCl<sub>2</sub> complexes were prepared. Treatment of the *exo,exo* (isodiCp)<sub>2</sub>TiCl<sub>2</sub> with MeLi gives (isodiCp)<sub>2</sub>TiClMe<sub>2</sub>. However, treatment of the *endo,endo* and *endo,exo* (isodiCp)<sub>2</sub>TiCl<sub>2</sub> does not lead to stable products under analogous conditions. Treatment of all three (isodiCp)<sub>2</sub>TiCl<sub>2</sub> isomers with  $\text{C}_6\text{F}_5\text{Li}$  gives the corresponding air stable, (isodiCp)<sub>2</sub>Ti( $\text{C}_6\text{F}_5$ )Cl.<sup>108</sup> Reduction of *exo,exo* (isodiCp)<sub>2</sub>TiCl<sub>2</sub> gives *exo,exo* (isodiCp)<sub>2</sub>TiCl, or in the presence of BMTA (isodiCp)<sub>2</sub>TiCl(Me<sub>3</sub>SiC≡CSiMe<sub>3</sub>).<sup>109</sup>

Paquette has shown that lithium salts of annulated cyclopentadienides coordinate to a metal atom predominantly or exclusively from a single  $\pi$  surface. Paquette has proposed that this facial selectivity is controlled by the locus of the lithium counterion and the state of aggregation of the reactive organometallic species. Recently, Paquette and Sivik have shown that it is possible to take advantage of the high stereoselectivity of *C*-silylation of annulated cyclopentadienides and the strict inversion of configuration that occurs during electrophilic condensation of these silanes with titanium chloride reagents, as shown in Scheme 7.<sup>110</sup>

#### 9.4 *ansa*-Metalloenes

There has been considerable interest in the synthesis of *ansa*-metalloenes of the group 4 transition metals because of their potential use as reagents or catalysts in organic synthesis. The bridging of the two rings in an *ansa*-metalloene can, if the bridge is short enough, cause significant changes in the ring centroid-Ti-ring centroid angle and give a more open coordination geometry. In addition, the bridging of the two

Scheme 7

rings can 'lock' substituents on the two rings relative to each other.

Many *ansa*-metallocene complexes of titanium are best prepared by treatment of  $\text{TiCl}_3$  or  $\text{TiCl}_3\text{THF}_3$  with the dianion of a bridged dicyclopentadienyl ligand, followed by an oxidative work-up. Simple *ansa*-metalloenes (**29**) have been prepared with hydrocarbon bridges ( $\text{CH}_2\text{CH}_2\text{CH}_2$ ,<sup>111</sup>  $\text{CMe}_2\text{CMe}_2$ ,<sup>112</sup>  $\text{CMe}_2$ <sup>113</sup>) rigid hydrocarbon bridges,  $\text{C}(\text{=CH}_2)\text{C}(\text{=NR}_2)$ ,<sup>114</sup> and heteroatom containing bridges,  $\text{SiMe}_2$ ,<sup>115</sup>  $\text{Me}_2\text{Si}(\text{CH}_2)_3\text{SiMe}_2$ ,<sup>116</sup>  $\text{Me}_2\text{SiN(R)SiMe}_2$ ,<sup>117</sup>  $\text{Me}_2\text{SiOSiMe}_2$ .<sup>99</sup> *ansa*-metalloenes incorporating permethylated cyclopentadienyl rings (**30**) have been prepared with  $\text{CMe}_2$ ,<sup>118</sup>  $\text{GeMe}_2$ ,<sup>119,120</sup>  $\text{PPh}$ <sup>121</sup> bridges and a smaller number of *ansa*-metalloene have been prepared the incorporate one Cp and one Cp\* bridged by  $\text{SiMe}_2$ ,<sup>122</sup>  $\text{GeMe}_2$ ,<sup>122,123</sup> Treatment of the lithium salts 1,2-bis(1-indenyl)benzenes with  $\text{TiCl}_3$  followed by oxidation gives the phenyl-bridged *ansa*-bis(indenyl)titanium dichloride in good yield.<sup>124</sup> Several *ansa*-metalloenes bridged at the 7,7'-positions of the indenyl moiety have been prepared.<sup>125</sup>

A small number of alkene-linked *ansa*-metalloenes are known for titanium. Thus reaction of  $\text{Na}_2(\text{C}_5\text{H}_4)\text{C(R)=C(R)}(\text{C}_5\text{H}_4)$  with  $\text{TiCl}_4$  or  $\text{TiCl}_3\text{THF}_3$  affords the corresponding alkene-bridged *ansa*-titanocene dichlorides. There is no indication of interaction between the alkene  $\pi$ -system and the titanium center.<sup>126</sup>

*ansa*-Metallocenes of titanium dichloride undergo many of the same reactions as the unbridged analogs. For example, reduction of  $(\text{Me}_2\text{SiCp}_2)\text{TiCl}_2$  with Na/Hg gives the corresponding dimeric titanium(III) *ansa*-metallocene  $[(\text{Me}_2\text{SiCp}_2)\text{TiCl}]_2$ . Treatment of  $[(\text{Me}_2\text{SiCp}_2)\text{TiCl}]_2$  with  $\text{PMe}_2\text{Ph}$  or reduction of  $(\text{Me}_2\text{SiCp}_2)\text{TiCl}_2$  with Na/Hg in the presence of  $\text{PMe}_2\text{Ph}$  forms  $(\text{Me}_2\text{SiCp}_2)\text{TiCl}(\text{PMe}_2\text{Ph})$ . Alkylation of  $(\text{Me}_2\text{SiCp}_2)\text{TiCl}(\text{PMe}_2\text{Ph})$  leads to the titanium(III) alkyls  $[(\text{Me}_2\text{SiCp}_2)\text{TiR}(\text{PMe}_2\text{Ph})]$ .<sup>127</sup>

*ansa*-Metallocenes have been prepared in which the two cyclopentadienyl rings are differently substituted. For example, treatment of  $\text{TiCl}_4$  with the unsymmetrical dianions  $(\text{C}_5\text{H}_4)\text{CHR}(\text{Cp}')^{2-}$  ( $\text{R} = \text{Me}, \text{CMe}_3$ ;  $\text{Cp}' = \text{Cp}, \text{indenyl}, \text{fluorenyl}$ ) affords the corresponding *ansa*-metallocenes  $[(\text{C}_5\text{H}_4)\text{CHR}(\text{Cp}')]\text{TiCl}_2$ .<sup>128</sup>

*ansa*-Metallocenes and, in particular, chiral *ansa*-metallocenes have generated considerable interest because of their use as reagents and catalysts to carry out stereoselective polymerization, hydrogenation, alkylation of ketones, and aminoalkylation of alkynes.

Addition of a substituent, such as an alkyl group or a fused ring, to the cyclopentadienyl group in *ansa*-metallocenes leads to the possibility of racemic and meso complexes. For example, ethylenebis(1-indenyl) and ethylenebis(tetrahydro-1-indenyl) complexes prepared by Brintzinger and coworkers have been isolated in both the racemic form (31) and meso form (32).<sup>129–131</sup>

Titanium *ansa*-metallocenes incorporating a  $\text{SiMe}_2$  or  $\text{CMe}_2\text{CMe}_2$  bridge and a Ph or 1-naphthyl substituent in one  $\beta$ -position of each Cp ring have been prepared as a mixture of racemic and meso complexes.<sup>132</sup> Synthesis of the racemic and meso diastereomers of disubstituted tetramethylethanediybridged titanocene derivatives  $\text{Me}_4\text{C}_2(1-\text{C}_5\text{H}_3-3-\text{R})_2\text{TiCl}_2$  ( $\text{R} = t\text{-Bu}, \text{SiMe}_3, i\text{-Pr}, \alpha, \alpha\text{-dimethylbenzyl}, \text{or } 1\text{-phenylcyclohexyl}$ ) is accomplished by reductive coupling of the appropriately substituted 6,6-dimethylfulvenes with  $\text{Mg}/\text{CCl}_4$  and reaction of the resulting di-Grignard reagents with  $\text{TiCl}_3 \cdot 3\text{THF}$ , followed by oxidative work-up.<sup>133</sup>

Several titanium *ansa*-metallocenes have been prepared which incorporate chiral centers in the backbone as a way of influencing the stereoselectivity of *ansa*-metallocene formation. Chiral backbones that have been

prepared and used in this fashion include (1*R*, 2*R*)-*trans*-1,2-bis(1-indenylmethyl)cyclopentane,<sup>134</sup> (*S*, *S*)-2,3-butylene-1,1'-bis(indenyl),<sup>135</sup> and 2,3-bis[3-(1,1-dimethylethyl)-1,3-cyclopentadien-5-yl]-2,3-dimethylbutane.<sup>136</sup> Chiral *ansa*-metallocene such as  $(\eta^5:\eta^5\text{-C}_5\text{Me}_4\text{SiMe}_2\text{C}_5\text{H}_3\text{R}^*)\text{TiCl}_2$  ( $\text{R}^* = \text{menthyl}, \text{neomenthyl}$ ) incorporating a chiral group on one of the Cp rings have been prepared.<sup>137</sup> Chiral *ansa* complexes utilizing annulated cyclopentadienyl ligands have also been prepared.<sup>138</sup> Chiral *ansa*-metallocene complexes based upon biphenyl and binaphthyl bridges have been prepared.<sup>139–144</sup> The chiral annulated *ansa*-metallocenes such as (+)-[ethylene-1,2-bis( $\eta^5$ -(1*R*, 7*R*, 8*R*, 10*R*)-8,10-dimethyltricyclo[5.2.2.0<sup>2,6</sup>]-2,5-undecadien-4-yl)]titanium dichloride (33) has been prepared.<sup>145</sup>

Collins and coworkers have developed two synthetic routes for the preparation of chiral [1,2-ethylenebis( $\eta^5$ -3-alkylcyclopentadienyl)]titanium dichlorides ( $\text{R} = \text{Me}, \text{Et}, i\text{-Pr}, t\text{-Bu}$ ) in 80–85% yields as a mixture of racemic and meso-titanocene dichlorides.<sup>146</sup> In more recent work, the addition of a methyl group to the cyclopentadienyl rings has allowed Collins and coworkers to prepare a series of [1,2-ethylene-1,1'-bis(4-*R*-2-methylcyclopentadienyl)] titanium dichlorides ( $\text{R} = \text{Me}, i\text{-Pr}, t\text{-Bu}$ ) stereoselectively to give the racemic isomers.<sup>147</sup>

Biscyclopentadienyl incorporating reactive functional groups on each Cp ring have been utilized to prepare *ansa*-metallocenes. Thus, treatment of  $(\eta^5\text{-C}_5\text{H}_4\text{SiClMe}_2)_2\text{TiCl}_2$  with a stoichiometric amount of water with selective hydrolysis of the Si-Cl bonds to gives the tetramethyldisiloxane-bridged dicyclopentadienyl complexes  $[(\eta^5\text{-C}_5\text{H}_4)\text{SiMe}_2\text{OSiMe}_2(\eta^5\text{-C}_5\text{H}_4)]\text{TiCl}_2$ .<sup>99</sup> In an analogous manner, treatment of  $(\text{Cp-P-}t\text{-BuCl})_2\text{CMe}_2$  with one equivalent of  $\text{TiCl}_4$  in the presence of  $\text{Et}_3\text{N}$  gives complex  $[(\text{Cp-P-}t\text{-BuCl})_2\text{CMe}_2]\text{TiCl}_2$ .<sup>101</sup>

Cationic *ansa*-( $\eta^5$ -cyclopentadienyl)( $\eta^6$ -arene) titanium derivatives have been prepared with both Cp and Cp\* derivatives. Treatment of  $\text{TiCl}_4$  with  $\text{C}_5\text{H}_4(\text{R})\text{SiMe}_3$  ( $\text{R} = \text{CMe}_2\text{Ph}, \text{CMe}_2\text{CH}_2\text{Ph}, \text{CHPh}_2$ ) gives the corresponding half-sandwich complexes  $(\eta^5\text{-C}_5\text{H}_4\text{R})\text{TiCl}_3$ . Alkylation of  $(\eta^5\text{-C}_5\text{H}_4\text{R})\text{TiCl}_3$  gives  $(\eta^5\text{-C}_5\text{H}_4\text{R})\text{TiMe}_3$  which upon treatment with  $[\text{Ph}_3\text{C}]^+ [\text{B}(\text{C}_6\text{F}_5)_4]^-$  in dichloromethane at low temperature gives the cationic  $[(\eta^5\text{-C}_5\text{H}_4\text{R})\text{TiMe}_2]^+$  *ansa* complexes; with  $\pi$ -coordination of the Ph ring with one-

and two-carbon bridges.<sup>148</sup> An analogous permethyl complex  $[(\eta^5, \eta^6\text{-C}_5\text{H}_4\text{CMe}_2\text{Ar})\text{TiMe}_2][\text{MeB}(\text{C}_6\text{F}_5)_3]$  is prepared by treatment of  $(\eta^5\text{-C}_5\text{H}_4\text{CMe}_2\text{Ar})\text{TiMe}_3$  ( $\text{Ar} = 3, 5\text{-Me}_2\text{C}_6\text{H}_3$ ) with  $\text{B}(\text{C}_6\text{F}_5)_3$ . Treatment of  $(\eta^5\text{-C}_5\text{H}_4\text{CMe}_2\text{Ar})\text{TiMe}_3$  with  $\text{B}(\text{C}_6\text{F}_5)_3$  in bromobenzene give the unusual dimeric Ti(III) dicationic *ansa*-metallocene,  $\{[(\eta^5, \eta^6\text{-C}_5\text{H}_4\text{CMe}_2\text{Ar})\text{Ti}(\mu\text{-Br})_2][\text{B}(\text{C}_6\text{F}_5)_4]_2\}$ .<sup>149</sup>

### 9.5 Cationic Bis(cyclopentadienyl)titanium Complexes

Since cationic titanium complexes have been proposed as intermediates in alkene polymerization by soluble  $\text{Cp}_2\text{TiCl}_2/\text{AlR}_3$ -based Ziegler–Natta catalysts (see *Ziegler–Natta Catalysts*), there has been considerable interest in the synthesis and reactivity of cationic titanium complexes (see *Oligomerization & Polymerization by Homogeneous Catalysis*).

The reaction of  $\text{Cp}_2\text{TiCl}_2$  with  $\text{AgAsF}_6$  or the reaction of  $\text{Cp}_2\text{TiF}_2$  with  $\text{AsF}_5$ , in  $\text{SO}_2$ , gives  $\text{Cp}_2\text{Ti}(\text{AsF}_6)_2$  in quantitative yields.<sup>150</sup> The reaction of  $\text{Cp}_2\text{Ti}(\text{AsF}_6)_2$  in  $\text{SO}_2$  with  $\text{HCN}$ ,  $\text{ICN}$ ,  $\text{AsMe}_3$ , or  $\text{As}_2\text{Me}_4$  affords the new cationic titanocene complexes  $[\text{Cp}_2\text{Ti}(\text{HCN})_2][\text{AsF}_6]_2$ ,  $[\text{Cp}_2\text{Ti}(\text{ICN})_2][\text{AsF}_6]_2$ ,  $[\text{Cp}_2\text{Ti}(\text{AsMe}_3)_2][\text{AsF}_6]_2$ , and  $[\text{Cp}_2\text{Ti}(\text{As}_2\text{Me}_4)_2][\text{AsF}_6]_4$ .<sup>151</sup> Treatment of  $\text{Cp}_2\text{TiCl}_2$  with 2 equivalent of  $\text{AgSbF}_6$  in  $\text{SO}_2$  gives  $\text{Cp}_2\text{Ti}(\text{SbF}_6)_2$  and  $\text{AgCl}$  quantitatively.<sup>152</sup>

Treatment of  $\text{Cp}_2\text{Ti}(\text{O}_2\text{CPh})_2$  with  $\text{H}_2\text{SO}_4$  or  $\text{H}_2\text{SeO}_4$  in  $\text{Ac}_2\text{O}$  forms  $[\text{Cp}_2\text{Ti}(\text{H}_2\text{O})_2]\text{SO}_4$  and  $\text{Cp}_2\text{TiSeO}_4$  in 85 and 78% yield, respectively. Reaction of  $\text{Cp}_2\text{TiCl}_2$  with 4 M  $\text{H}_2\text{SO}_4$  and  $\text{K}_2\text{Cr}_2\text{O}_7$  gives  $[\text{Cp}_2\text{Ti}(\text{H}_2\text{O})_2]\text{Cr}_2\text{O}_7$  in 50% yield.  $\text{Cp}_2\text{TiSeO}_4$  and  $[\text{Cp}_2\text{Ti}(\text{H}_2\text{O})_2]\text{Cr}_2\text{O}_7$  are found to be explosive when heated or mechanically agitated.<sup>153</sup>

$[\text{Cp}_2^*\text{Ti}(\text{DMF})\text{Cl}]\text{CF}_3\text{SO}_3$  and  $[\text{Cp}_2^*\text{Ti}(\text{DMF})_2](\text{CF}_3\text{SO}_3)_2$  have been prepared by reaction of  $\text{Cp}_2^*\text{TiCl}_2$  with  $\text{CF}_3\text{SO}_3\text{Ag}$  in DMF. The structures of  $[\text{Cp}_2^*\text{Ti}(\text{DMF})\text{Cl}]\text{CF}_3\text{SO}_3$  and  $[\text{Cp}_2^*\text{Ti}(\text{DMF})_2](\text{CF}_3\text{SO}_3)_2$  have been determined by X-ray diffraction, and the titanium atom in each of these complexes was found to have the expected, approximately tetrahedral, coordination geometry typical for  $\text{Cp}_2^*\text{Ti}^{\text{IV}}$  complexes.<sup>154</sup>

The reaction of  $\text{Cp}_2\text{Ti}(\text{CF}_3\text{SO}_3)_2$  with bipy or phen forms  $[\text{Cp}_2\text{Ti}(\text{bipy})](\text{CF}_3\text{SO}_3)_2$  and  $[\text{Cp}_2\text{Ti}(\text{phen})](\text{CF}_3\text{SO}_3)_2$ , respectively. An X-ray structure determination indicates that the Ti atoms are to a first approximation tetrahedrally coordinated, and the atoms of the bipy or phen chelate ligands are nearly coplanar.<sup>155</sup>

Reaction of  $\text{Cp}_2\text{TiCl}_2$  with Zn in the presence of MeCN gives  $[\text{Cp}_2\text{Ti}(\text{MeCN})_2][\text{ZnCl}_4]$ . Treatment of  $[\text{Cp}_2\text{Ti}(\text{MeCN})_2][\text{BPh}_4]$  with  $\text{PMe}_3$  in a stepwise fashion forms  $[\text{Cp}_2\text{Ti}(\text{MeCN})(\text{PMe}_3)][\text{BPh}_4]$  initially, and then  $[\text{Cp}_2\text{Ti}(\text{PMe}_3)_2][\text{BPh}_4]$  upon addition of excess  $\text{PMe}_3$ . Similar reaction of  $[\text{Cp}_2\text{Ti}(\text{MeCN})_2][\text{BPh}_4]$  with excess  $\text{PEt}_3$  gives only the monosubstitution product  $[\text{Cp}_2\text{Ti}(\text{MeCN})(\text{PEt}_3)][\text{BPh}_4]$ .  $\text{PCy}_3$  and  $\text{PPh}_3$  fail to react with  $[\text{Cp}_2\text{Ti}(\text{MeCN})_2][\text{BPh}_4]$ .<sup>156</sup>

Nitrile complexes of the type  $[\text{Cp}_2\text{TiMe}(\text{N}\equiv\text{CR})]\text{BPh}_4$  ( $\text{R} = \text{Me}, \text{Pr}, t\text{-Bu}, \text{Ph}$ ) react with excess nitrile in  $\text{CH}_2\text{Cl}_2$  at room temperature to give azaalkenyldiene complexes,  $[\text{Cp}_2\text{Ti}(\text{N}=\text{CMeR})(\text{N}\equiv\text{CR})]\text{BPh}_4$ , in quantitative yield by migratory insertion (see *Migratory Insertion*) of nitrile into the Ti–Me bond (equation 33). The indenyl complexes  $[\text{Ind}_2\text{Me}(\text{N}\equiv\text{CR})]\text{BPh}_4$  are more reactive with nitriles than are the corresponding cyclopentadienyl complexes  $[\text{Cp}_2\text{TiMe}(\text{RCN})]\text{BPh}_4$ . The structure of  $[(\text{C}_9\text{H}_7)_2\text{Ti}(\text{NCMePh})(\text{NCPh})]\text{BPh}_4$  has been determined by X-ray crystallography. The Ti–azavinyldiene arrangement is linear, with a short Ti–N double bond; the Me and Ph substituents adopt a Me-outside conformation in the plane bisecting the indenyl–Ti–indenyl angle. The indenyl ring centroid–titanium–indenyl ring centroid angle is  $135.8(6)^\circ$ .<sup>157</sup>

(33)

$[\text{Cp}_2\text{TiMe}(\text{L})]\text{BPh}_4$  ( $\text{L} = \text{MeCN}, \text{PrCN}, t\text{-BuCN}, \text{PhCN}, \text{Me}_3\text{P}, \text{Me}_2\text{PPh}, \text{MePPh}_2, \text{Bu}_3\text{P}, \text{py}$ ) have been prepared in high yields by treating  $\text{Cp}_2\text{TiMeCl}$  with  $\text{L}$  and  $\text{NaBPh}_4$  in polar solvents (equation 34). In a similar manner, treatment of  $\text{Ind}_2\text{TiMeCl}$  with  $\text{L}$  ( $\text{L} = \text{MeCN}, \text{PrCN}, t\text{-BuCN}, \text{PhCN}, \text{Me}_3\text{P}, \text{Me}_2\text{PPh}$ ) and  $\text{NaBPh}_4$  gives the corresponding complexes  $[\text{Ind}_2\text{TiMe}(\text{L})]\text{BPh}_4$ . The nitrile complexes readily undergo substitution with pyridine or  $\text{PMe}_3$ , but fail to react with  $\text{PhC}\equiv\text{CR}$  ( $\text{R} = \text{SiMe}_3, \text{Me}, \text{Ph}$ ). Treatment of  $[\text{Cp}_2\text{TiMe}(\text{MeCN})]\text{BPh}_4$  with 1 atm of CO forms the  $\eta^2$ -acyl complex  $[\text{Cp}_2\text{Ti}(\eta^2\text{-COMe})(\text{MeCN})]\text{BPh}_4$  in which the nitrile ligand has been retained. Addition of  $t\text{-BuNC}$  to  $[\text{Cp}_2\text{TiMe}(\text{MeCN})]\text{BPh}_4$  in acetonitrile gives  $[\text{Cp}_2\text{Ti}(\eta^2\text{-C}(\text{Me})=\text{N}-t\text{-Bu})(\text{C}\equiv\text{N}-t\text{-Bu})(\text{MeCN})]\text{BPh}_4$ .<sup>158</sup>

$\text{L} = \text{MeCN}, \text{PrCN}, t\text{-BuCN}, \text{Me}_3\text{P}, \text{Me}_2\text{PPh}, \text{MePPh}_2, \text{Bu}_3\text{P}, \text{Py}$

Reaction of  $\text{Cp}_2\text{TiMe}_2$  and  $\text{Ind}_2\text{TiMe}_2$  with  $(\text{PhNMe}_2\text{H})\text{BPh}_4$  or  $(\text{Bu}_3\text{NH})\text{BPh}_4$  in  $\text{CD}_2\text{Cl}_2$  forms the corresponding base-free cationic 14-electron alkyltitanium complexes  $[\text{Cp}_2\text{TiMe}]\text{BPh}_4$  and  $[\text{Ind}_2\text{TiMe}]\text{BPh}_4$ . Treatment of  $[\text{Ind}_2\text{TiMe}]\text{BPh}_4$  with  $\text{Et}_2\text{O}$  forms black crystals of  $[\text{Ind}_2\text{TiMe}(\text{OEt}_2)]\text{BPh}_4$ , whereas reaction of  $[\text{Cp}_2\text{TiMe}]\text{BPh}_4$  with MeCN yields  $[\text{Cp}_2\text{TiMe}(\text{NCMe})]\text{BPh}_4$ .  $[\text{Cp}_2\text{TiMe}]\text{BPh}_4$  and  $[\text{Ind}_2\text{TiMe}]\text{BPh}_4$  catalytically polymerize ethylene.<sup>159</sup> The oxidation of  $\text{Cp}_2^*\text{TiMe}$  with  $\text{AgBPh}_4$  in THF gives  $[\text{Cp}_2^*\text{TiMe}(\text{THF})]\text{BPh}_4$ .<sup>160</sup>

The reaction of  $\text{CpTiCl}_3$  with  $\text{AgAsF}_6$  and  $\text{AgSbF}_6$  in  $\text{SO}_2$  at  $-50^\circ\text{C}$  forms  $\text{CpTi}(\text{AsF}_6)_3\cdot\text{SO}_2$  and  $\text{CpTi}(\text{SbF}_6)_3\cdot\text{SO}_2$ .

$\text{CpTi}(\text{AsF}_6)_3 \cdot \text{SO}_2$  and  $\text{CpTi}(\text{SbF}_6)_3 \cdot \text{SO}_2$  are Lewis acid adducts of  $\text{CpTiF}_3$ .  $\text{CpTi}(\text{AsF}_6)_3 \cdot \text{SO}_2$  and  $\text{CpTi}(\text{SbF}_6)_3 \cdot \text{SO}_2$  decompose in solution at room temperature and slowly at  $-50^\circ\text{C}$ , but are nonexistent in the solid state.<sup>161</sup>

## 10 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(III)

Dang and Geise have reviewed the reduction of  $\text{Cp}_2\text{TiCl}_2$  to  $[\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2]$ . This reduction has been carried out using Al, K, Na, Zn, or lithium and sodium amalgams.<sup>162</sup> Alternatively, treatment of  $\text{Cp}_2\text{TiCl}_2$  with  $\text{LiAlH}_4$ ,  $\text{NaBH}_4$ ,  $\text{MgH}_2$ , bulky Grignard reagents (see *Grignard Reagents*), and organoaluminum and organolithium reagents also leads to  $\text{Ti}^{\text{III}}$  species. Electrochemical and photochemical procedures to produce  $\text{Ti}^{\text{III}}$  have also been investigated.<sup>163</sup> In the reduction of  $\text{Cp}_2\text{TiCl}_2$  with Zn the intermediate  $(\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2)_2\text{Zn}$  has been isolated and characterized (equation 35).<sup>164</sup> The reduction of  $\text{Cp}_2\text{TiCl}_2$  with Mg in THF in the presence of  $\text{P}_4$  leads to  $(\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2)_2\text{Mg}(\text{THF})_2$  and  $(\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2)_2\text{Mg}(\text{THF})_2(\mu\text{-Cl})_2$ , which have been characterized also. Reaction of  $(\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2)_2\text{Mg}(\text{THF})_2$  and  $(\text{Cp}_2\text{Ti}(\mu\text{-Cl})_2)_2\text{Mg}(\text{THF})_2(\mu\text{-Cl})_2$  with  $\text{PMe}_3$  forms  $\text{Cp}_2\text{Ti}(\text{PMe}_3)\text{Cl}$ , which upon reduction with Mg in the presence of  $\text{PMe}_3$  gives  $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2$ .<sup>165</sup>

Treatment of  $\text{Cp}_2\text{TiCl}_2$  and  $\text{CpTiCl}_3$  with  $[\text{Li}[\mu\text{-P}(\text{SiMe}_3)_2](\text{THF})_2]_2$  in THF at room temperature leads to the reduced species  $\text{Cp}_2\text{TiCl}(\text{THF})$  and  $\text{CpTiCl}_2(\text{THF})$ , respectively, in high yields.<sup>166</sup>

Reaction of  $\text{Cp}_2\text{Ti}(\text{CO})_2$  with  $\text{Cp}_2\text{TiBr}_2$  or  $\text{Cp}_2\text{TiCl}_2$  in  $\text{C}_6\text{H}_6$  forms  $[\text{Cp}_2\text{TiBr}]_2$  and  $[\text{Cp}_2\text{TiCl}]_2$ , respectively, in 90% yield.<sup>167</sup> An ESR study of the reaction solution of the reaction of  $\text{Cp}_2\text{Ti}(\text{CO})_2$  with  $\text{Cp}_2\text{TiBr}_2$  indicates the presence of  $[\text{Cp}_2\text{TiBr}]$  in equilibrium with the dimer, as well as the presence of the unstable intermediate  $[\text{Cp}_2\text{Ti}(\text{CO})\text{Br}]$ .<sup>168</sup>

Reduction of  $\text{Cp}_2\text{TiCl}_2$  with 1.5 equivalent of  $\text{Na}(\text{Hg})$  gives a mixture of the dinuclear fulvalene complexes  $[\text{CpTi}(\mu\text{-Cl})_2(\mu\text{-}\eta^5\text{:}\eta^5\text{-C}_{10}\text{H}_8)]$  (**34**) and  $[\text{CpTi}(\mu\text{-H})_2(\mu\text{-}\eta^5\text{:}\eta^5\text{-C}_{10}\text{H}_8)]$  ('titanocene') (**35**) in 40% yield each (equation 36). Both compounds contain  $\text{Ti}^{\text{III}}$  species, which undergo quick oxidation upon exposure to air, yielding  $[\text{CpTiCl}]_2(\mu\text{-O})(\mu\text{-}\eta^5\text{:}\eta^5\text{-C}_{10}\text{H}_8)$ . Reduction of  $[\text{CpTi}(\mu\text{-Cl})_2(\mu\text{-}\eta^5\text{:}\eta^5\text{-C}_{10}\text{H}_8)]$

with  $\text{LiBHET}_3$  gives  $[\text{CpTi}(\mu\text{-H})_2(\mu\text{-}\eta^5\text{:}\eta^5\text{-C}_{10}\text{H}_8)]$ .<sup>169</sup>

The chemistry of the Ti-C bond in  $\text{Cp}_2\text{TiR}$  has been reviewed.<sup>170</sup> The paramagnetic, 15-electron,  $d^1$  titanium complexes  $\text{Cp}_2^*\text{TiR}$  ( $\text{R} = \text{Me}, \text{Et}, \text{Pr}, \text{CH}_2\text{-}i\text{-Bu}, \text{CH}_2\text{Ph}, \eta^3\text{-C}_3\text{H}_5, \eta^3\text{-C}_4\text{H}_7, \text{CH}=\text{CH}_2, \text{C}\equiv\text{CMe}, \text{Ph}$ ) have been prepared by the reaction of  $\text{Cp}_2^*\text{TiCl}$  with the corresponding anion (equation 37). The ethyl and *n*-propyl complexes,  $\text{Cp}_2^*\text{TiEt}$  and  $\text{Cp}_2^*\text{TiPr}$ , have also been prepared by the addition of ethylene or propylene, respectively, to  $\text{Cp}_2^*\text{TiH}$  (equation 38). Treatment of  $\text{Cp}_2^*\text{TiR}$  with CO at approx.  $-70^\circ\text{C}$  in pentane or toluene leads to the formation of the corresponding  $\eta^2$ -acyl complexes, which are thermally stable up to  $0^\circ\text{C}$  (equation 39). Above  $0^\circ\text{C}$ , these acyl complexes are unstable, leading to  $\text{Cp}_2^*\text{Ti}(\text{CO})_2$  and unidentified paramagnetic products. Treatment of  $\text{Cp}_2^*\text{TiMe}$  with  $t\text{-BuN}\equiv\text{C}$  gives the corresponding  $\eta^2$ -iminoacyl complex  $\text{Cp}_2^*\text{Ti}(\text{CMe}=\text{N-}t\text{-Bu})$ . Reaction of  $\text{CO}_2$  with  $\text{Cp}_2^*\text{TiR}$ , in which the R group does not contain a  $\beta$ -hydrogen, gives the corresponding carboxylate complexes  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-O}_2\text{CR})$ . However, treatment of alkyl complexes  $\text{Cp}_2^*\text{TiR}$ , in which the R group bears a  $\beta$ -hydrogen, with  $\text{CO}_2$  forms the formate complex  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-O}_2\text{CH})$  as the dominant product (equation 40). This formate complex is produced by  $\beta$ -H transfer to the incoming  $\text{CO}_2$  and extrusion of an alkene. These  $\text{Cp}_2^*\text{TiR}$  complexes are surprisingly unreactive toward  $\text{CH}_2=\text{CH}_2$ , with  $\text{Cp}_2^*\text{TiMe}$  recovered unchanged even after treatment with 10 atm of  $\text{CH}_2=\text{CH}_2$  at  $50^\circ\text{C}$  for 100 h.<sup>171</sup>

Further studies have been carried out on  $\text{Cp}_2^*\text{TiMe}$  and  $\text{Cp}_2^*\text{TiEt}$ . Reaction of  $\text{Cp}_2^*\text{TiMe}$  and  $\text{Cp}_2^*\text{TiEt}$  with  $\text{HO}_2\text{C-}i\text{-Pr}$ ,  $\text{HOEt}$ , or  $\text{HC}\equiv\text{CMe}$  forms  $\text{Cp}_2^*\text{TiO}_2\text{C-}i\text{-Pr}$ ,  $\text{Cp}_2^*\text{TiOEt}$ , and  $\text{Cp}_2^*\text{TiC}\equiv\text{CMe}$ , respectively, and  $\text{RH}$ . Reaction of  $\text{Cp}_2^*\text{TiMe}$

with neat  $\text{MeC}\equiv\text{CMe}$  gives  $\text{Cp}_2^*\text{TiC}(\text{Me})=\text{CMe}_2$  via migratory insertion (see *Migratory Insertion*); however,  $\text{PhC}\equiv\text{CPh}$  and  $\text{Me}_3\text{SiC}\equiv\text{CSiMe}_3$  are unreactive toward  $\text{Cp}_2^*\text{TiMe}$ .

The  $\beta$ -H atom of the ethyl group in  $\text{Cp}_2^*\text{TiEt}$  exhibits agostic bonding (see *Agostic Bonding*) with the titanium.  $\text{Cp}_2^*\text{TiEt}$  reacts with  $t\text{-BuC}\equiv\text{N}$ ,  $\text{Me}_2\text{C}=\text{O}$ , and alkynes via a  $\text{Cp}_2^*\text{TiH}$  intermediate to give products of migratory insertion into the Ti-H bond of  $\text{Cp}_2^*\text{TiH}$ .<sup>172</sup>

Oxidative alkylation of  $\text{Cp}_2^*\text{TiX}$  ( $\text{X} = \text{OMe}, \text{Cl}, \text{N}=\text{CH}-t\text{-Bu}$ ) and  $\text{Cp}_2^*\text{TiMe}$  by  $\text{CdMe}_2$  or  $\text{ZnMe}_2$  forms the diamagnetic complexes  $\text{Cp}_2^*\text{Ti}(\text{Me})\text{X}$  and  $\text{Cp}_2^*\text{TiMe}_2$ , respectively, and cadmium or zinc metal (equation 41). Oxidative alkylation of  $\text{Cp}_2^*\text{TiR}$  ( $\text{R} = \text{Et}, \text{CH}=\text{CH}_2, \text{Ph}$ ) with  $\text{CdMe}_2$  or  $\text{ZnMe}_2$  forms a statistical mixture of  $\text{Cp}_2^*\text{Ti}(\text{Me})\text{R}$ ,  $\text{Cp}_2^*\text{TiMe}_2$ , and  $\text{Cp}_2^*\text{TiR}_2$ .<sup>173</sup> Oxidation of  $\text{Cp}_2^*\text{TiR}$  with  $\text{PbCl}_2$  gives  $\text{Cp}_2^*\text{Ti}(\text{R})\text{Cl}$  ( $\text{R} = \text{Me}, \text{Et}, \text{Pr}, \text{CH}=\text{CH}_2, \text{Ph}, \text{OPr}$ ) in good yield (equation 42).

Thermolysis of  $\text{Cp}_2^*\text{Ti}(\text{Me})\text{CH}=\text{CH}_2$ , prepared by the reaction of  $\text{Cp}_2^*\text{Ti}(\text{CH}=\text{CH}_2)\text{Cl}$  with  $\text{MeLi}$ , gives  $\text{Cp}^*(\eta^6\text{-C}_6\text{Me}_4\text{CH}_2)\text{TiCH}=\text{CH}_2$  via a vinylidene intermediate,  $\text{Cp}_2^*\text{Ti}=\text{C}=\text{CH}_2$ , formed by a rate-limiting vinylic  $\alpha$ -hydrogen abstraction.  $\text{Cp}_2^*\text{Ti}(\text{Me})\text{Ph}$  undergoes thermally induced decomposition to give  $\text{Cp}^*(\eta^6\text{-C}_6\text{Me}_4\text{CH}_2)\text{TiPh}$  and methane. This thermolysis occurs via *ortho*-hydrogen abstraction from the phenyl ligand, giving an *o*-phenylene intermediate, which can be trapped by  $\text{CO}_2$  to yield the titanacycle, as shown in Scheme 8.<sup>18</sup>

Thermolysis of  $\text{Cp}_2^*\text{TiR}$  ( $\text{R} = \text{Me}, \text{Et}, n\text{-Pr}, \text{C}_2\text{H}_5, \text{CH}_2\text{-}t\text{-Bu}, \text{Ph}$ ) forms  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{Ti}$  in high yield as the exclusive organometallic product, along with  $\text{RH}$  (equation 43). Kinetic measurements and deuterium-labeling studies show that this decomposition is catalyzed by  $\text{Cp}_2^*\text{TiH}$ , which is formed either by  $\beta$ -hydrogen elimination (see  *$\beta$ -Hydride Elimination*) from a titanium alkyl  $\text{Cp}_2^*\text{TiCH}_2\text{CH}_2\text{R}$  at low temperature or by hydrogenolysis of  $\text{Cp}_2^*\text{TiR}$  or  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{Ti}$ , deriving dihydrogen by elimination from  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{Ti}$  at elevated temperatures. Permethiltitanocene,  $\text{Cp}_2^*\text{Ti}$ , is found not to be an intermediate in

these thermolysis reactions.<sup>174</sup>

Treatment of  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{Ti}$  with  $\text{PbCl}_2$  gives  $\text{Cp}^*(\eta^6\text{-C}_5\text{Me}_4\text{CH}_2)\text{TiCl}$ , which reacts with  $\text{C}\equiv\text{N}(2,6\text{-Me}_2\text{C}_6\text{H}_3)$  to give the  $\eta^1$ -iminoacyl complex (36). Reaction of iminoacyl (28) with a second equivalent of isonitrile gives (37).<sup>175</sup>

The titanocene(III) complexes  $\text{Cp}_2\text{TiX}(\text{PMe}_3)$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I}, \text{Me}, \text{SMe}$ ) are readily prepared by *comproportionation* reactions of  $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2$  and  $\text{Cp}_2\text{TiX}_2$ . The products are characterized by EPR spectroscopy.<sup>176</sup>

## 11 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(II)

Bis-cyclopentadienyltitanium(II) species are unstable 14-electron  $d^2$  species, with one lone-electron pair and two vacant valence orbitals. The reactivity of ' $\text{Cp}_2\text{Ti}$ ' has been compared to carbenes. The interactions between the occupied and unoccupied orbitals can explain why ' $\text{Cp}_2\text{Ti}$ ' reacts with unsaturated compounds to give metallacycles (see *Metallacycle*).

Murry first prepared  $\text{Cp}_2\text{Ti}(\text{CO})_2$  via the high-pressure carbonylation of  $\text{Cp}_2\text{Ti}(\eta^1\text{-C}_5\text{H}_5)_2$  (equation 44).<sup>177</sup> The reduction and carbonylation of  $\text{Cp}_2\text{TiCl}_2$  to give  $\text{Cp}_2\text{Ti}(\text{CO})_2$

Scheme 8

was first achieved with Mg in the presence of CO. *Reductive carbonylation* (see *Reductive Carbonylation*) of  $\text{Cp}_2\text{TiCl}_2$  or  $\text{Cp}_2^*\text{TiCl}_2$  with Mg, activated with  $\text{HgCl}_2$ , and CO in THF affords  $\text{Cp}_2\text{Ti}(\text{CO})_2$  (equation 45) and  $\text{Cp}_2^*\text{Ti}(\text{CO})_2$ , respectively, in good yield.<sup>178</sup> In recent years a wide range of ring-substituted biscyclopentadienyl derivatives have been reductively carbonylated. This work has recently been reviewed by Sikora *et al.*<sup>179</sup>

Rausch and coworkers have shown that  $\text{Cp}_2\text{Ti}(\text{CO})_2$  reacts reversibly with  $\text{PF}_3$ , under irradiation, to give  $\text{Cp}_2\text{Ti}(\text{PF}_3)_2$  (equation 46). In contrast, treatment of  $\text{Cp}_2\text{Ti}(\text{CO})_2$  with  $\text{PEt}_3$  or  $\text{PPh}_3$  gives  $\text{Cp}_2\text{Ti}(\text{CO})\text{PEt}_3$  and  $\text{Cp}_2\text{Ti}(\text{CO})\text{PPh}_3$ , respectively, in good yield (equation 47).  $\text{Cp}_2\text{Ti}(\text{CO})\text{PEt}_3$  can serve as a convenient source of  $[\text{Cp}_2\text{Ti}(\text{CO})]$ . Thus, treatment of  $\text{Cp}_2\text{Ti}(\text{CO})\text{PEt}_3$  with alkynes,  $\text{RC}\equiv\text{CR}$  ( $\text{R} = \text{Ph}, \text{C}_6\text{F}_5$ ), or alkenes,  $\text{RO}_2\text{CCH}=\text{CHCO}_2\text{R}$  ( $\text{R} = \text{Me}, \text{Et}$ ), leads to the corresponding alkyne and alkene complexes,  $\text{Cp}_2\text{Ti}(\text{CO})(\eta^2\text{-RC}\equiv\text{CR})$  and  $\text{Cp}_2\text{Ti}(\text{CO})(\eta^2\text{-RO}_2\text{CCH}=\text{CHCO}_2\text{R})$ , respectively, in good yields (equation 48).<sup>180</sup>

Rausch and coworkers have also developed a convenient, high-yield synthesis for  $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2$ , which has often been referred to as stabilized ‘titanocene’ (see *Titanocene*), by utilizing Mg to reduce  $\text{Cp}_2\text{TiCl}_2$  in the presence of  $\text{PMe}_3$  (equation 49).<sup>181</sup>

The unique phosphine–carbon dioxide complex  $\text{Cp}_2\text{Ti}(\text{CO}_2)\text{PMe}_3$  is prepared by treatment of  $\text{Cp}_2\text{Ti}(\text{PMe}_3)_2$  with dry  $\text{CO}_2$  at  $-180^\circ\text{C}$  (equation 50). Slow thermal decomposition of  $\text{Cp}_2\text{Ti}(\text{CO}_2)\text{PMe}_3$  at room temperature leads principally to  $\text{Cp}_2\text{Ti}(\text{CO})_2$ .<sup>182</sup>

The titanium alkene complex  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  can be prepared in greater than 80% yield by the Na/Hg reduction of  $\text{Cp}_2^*\text{TiCl}_2$  in toluene under 700 torr of ethylene (equation 51), or in nearly quantitative yield by the addition of ethylene to  $[\text{Cp}_2^*\text{Ti}]_2(\mu\text{-N}_2)$  (equation 52).<sup>183</sup> Alternatively, treatment

of  $\text{Cp}_2^*\text{TiEtCl}$  with MeLi,  $\text{KCH}_2\text{Ph}$ , or  $\text{LiCH}=\text{CH}_2$  leads to  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-C}_2\text{H}_4)$  in quantitative yield and the formation of RH via  $\beta$ -hydride elimination (see  *$\beta$ -Hydride Elimination*).<sup>39</sup> This titanium ethylene complex undergoes facile displacement of the ethylene by two-electron donors. For example, reaction of  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  with CO or MeNC leads to quantitative displacement of alkene to give  $\text{Cp}_2^*\text{Ti}(\text{CO})_2$  (equation 53) or the thermally unstable  $\text{Cp}_2^*\text{Ti}(\text{CNMe})_2$ , respectively.<sup>183</sup>

$\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  undergoes a reversible reaction with  $\text{CH}_2=\text{CH}_2$  to give the corresponding unstable titanacyclopentane complex (equation 54). Addition of  $\text{MeC}\equiv\text{CH}$  to  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  at  $-50^\circ\text{C}$  gives a mixture of metallacycle (see *Metallacycle*) (38) and the propynyl ethyl tautomer (39) (equation 55), which over several days rearranges to (38). Treatment of  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  with *t*-BuC $\equiv$ CH affords rapidly and quantitatively the *t*-butylacetylide ethyl complex  $\text{Cp}_2\text{Ti}(\text{Et})(\text{C}\equiv\text{C-}t\text{-Bu})$  (40). In contrast to this result, reaction of  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  with 2-butyne over 8 h at  $25^\circ\text{C}$  gives quantitatively the metallacycle  $\text{Cp}_2^*\text{Ti}(\text{C}(\text{Me})=\text{C}(\text{Me})\text{CH}_2\text{CH}_2)$  (equation 56). However, reaction of  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  with diphenylacetylene yields the alkyne complex  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-PhC}\equiv\text{CPh})$  (equation 57). Reaction of  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  with 1 equivalent of acetonitrile at  $-50^\circ\text{C}$  results in quantitative formation of the metallacycloimine complex  $\text{Cp}_2^*\text{Ti}(\text{N}=\text{C}(\text{Me})\text{CH}_2\text{CH}_2)$ , which above  $-10^\circ\text{C}$  establishes an equilibrium with its metallacycloenamine tautomer (equation 58). Addition of  $\text{CO}_2$  to  $\text{Cp}_2^*\text{Ti}(\eta^2\text{-CH}_2=\text{CH}_2)$  at  $-78^\circ\text{C}$  gives  $\text{Cp}_2^*\text{Ti}(\text{OC}(\text{O})\text{CH}_2\text{CH}_2)$  (equation 59).<sup>184</sup>

$\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$ , which is readily prepared in large quantities by the reduction of  $\text{Cp}_2\text{TiCl}_2$  with magnesium in the presence of  $\text{Me}_3\text{SiC}\equiv\text{CSiMe}_3$ , serves as ready sources of The chemistry of  $\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  has been extensively reviewed by Rosenthal and coworkers.<sup>185,186</sup>

$\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  can release  $\text{Me}_3\text{SiC}\equiv\text{CSiMe}_3$  quantitatively under mild conditions to give the unstable highly reactive ‘ $\text{Cp}_2\text{Ti}$ ’, which can then react with a wide range of unsaturated molecules. Treatment of  $\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  with one equivalent of  $\text{PhC}\equiv\text{CPh}$  leads to exchange of the acetylene to give  $\text{Cp}_2\text{Ti}(\eta^2\text{-PhC}\equiv\text{CPh})$ , which on treatment with additional  $\text{PhC}\equiv\text{CPh}$  gives the corresponding metallocycle  $\text{Cp}_2\text{Ti}[\text{C}(\text{Ph})=\text{C}(\text{Ph})\text{C}(\text{Ph})=\text{C}(\text{Ph})]$ . This reaction is very general, working with a wide range of substituted Cp derivatives and a wide range of substituted and disubstituted acetylenes including  $\alpha,\omega$ -diynes,  $\text{RC}\equiv\text{C}(\text{CH}_2)_n\text{C}\equiv\text{CR}$  to give bicyclic titanacyclopentadienies.

Thermolysis of  $\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  in the absence of substrate gives  $[\text{CpTi}(\mu\text{-H})_2(\mu\text{-}\eta^5\text{-}\eta^5\text{-C}_{10}\text{H}_8)]$  (35), while thermolysis of  $[\text{C}_5\text{Me}_4(\text{SiMe}_3)]_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  gives on dissociation of  $\text{Me}_3\text{SiC}\equiv\text{CSiMe}_3$  in the absence of other ligands, stable, free  $[\text{C}_5\text{Me}_4(\text{SiMe}_3)]_2\text{Ti}$ , which cannot be prepared directly by the reduction of  $[\text{C}_5\text{Me}_4(\text{SiMe}_3)]_2\text{TiCl}_2$ .

Reaction of  $\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  with  $\text{B}(\text{C}_6\text{F}_5)_3$  in toluene leads via electrophilic substitution on one of the Cp rings to the zwitterionic titanium(III) complex  $\text{CpTi}[\eta^5\text{-C}_5\text{H}_4\text{B}(\text{C}_6\text{F}_5)_3]$ . Treatment of  $\text{Cp}_2\text{Ti}(\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3)$  with fullerene gives the unique fullerene complex  $\text{Cp}_2\text{Ti}(\eta^2\text{-C}_{60})$ .

$\text{Cp}_2\text{Ti}(\text{CO})_2$  and  $\text{Cp}_2^*\text{Ti}(\text{CO})_2$  react instantaneously with TCNE (tetracyanoethene) and TCNQ (7,7,8,8-tetracyano-*p*-quinodimethane) to give the corresponding highly air-sensitive monocarbonyl TCNE (41) and TCNQ complexes.

The  $\text{Cp}_2^*\text{Ti}(\text{CO})(\text{TCNE})$  and  $\text{Cp}_2^*\text{Ti}(\text{CO})(\text{TCNQ})$  complexes were characterized in the oxidized and reduced forms through cyclic voltammetry, EPR, IR, and UV-visible spectroelectrochemistry. While oxidation at rather low potentials yields labile carbonyltitanium(IV) species of the TCNE and TCNQ ligands, the reduction occurs stepwise at unusually negative potentials, first on the ligand (to yield coordinated  $\text{TCNE}^{2-}$  and  $\text{TCNQ}^{2-}$ ) and then on the metal, to form Ti(II).<sup>187</sup>

## 12 CONSTRAINED GEOMETRY TITANIUM COMPLEXES

Constrained geometry titanium complexes (42), also known as *ansa* half-sandwich complexes, are currently of great scientific and technological interest as precursors to a new generation of high activity, high selectively Ziegler–Natta (see *Ziegler–Natta Catalysts*) type  $\alpha$ -olefin polymerization catalysts. A wide range of constrained geometry titanium complexes incorporating a  $\eta^5$ -cyclopentadienyl derivative with a remote  $\eta^1$ -hetero atom tethered via a wide range of bridging groups have been prepared. These complexes incorporate rigid bridges such as phenolates and carboranes and flexible hydrocarbon chains, or a single intervening C, Si, B, or P attached to a N, O, or P. The vast majority of these complexes have been evaluated for their potential for upon activation with MAO, and so on, for Ziegler–Natta type  $\alpha$ -olefin polymerization (see *Oligomerization & Polymerization by Homogeneous Catalysis*).

A variety of synthetic methods have been developed for the preparation cyclopentadienyl-phenoxytitanium

derivatives. Reaction of  $\text{TiCl}_4$  with the corresponding dilithio salts 2-(3,4-diphenylcyclopentadienyl)-6-phenylphenol derivatives gives the corresponding constrained geometry complexes.<sup>188</sup> Treatment of  $\text{TiCl}_4$  with one equivalent of a 2-tetramethylcyclopentadienyl phenol derivative to give a coordination intermediates, followed by treatment with 2 equivalent of  $n\text{-BuLi}$  at low temperature gives tetramethylcyclopentadienyl-phenoxytitanium dichlorides in moderate yields.<sup>189</sup> Treatment of  $\text{Ti}(\text{CH}_2\text{Ph})_4$  with 2-(tetramethylcyclopentadienyl)-4-methylphenol at  $60^\circ$  in toluene cleanly gives  $(\eta^1\text{-OC}_6\text{H}_3(\text{CH}_3)\text{-}\eta^5\text{-C}_5\text{Me}_4)\text{Ti}(\text{CH}_2\text{Ph})_2$  (43). In solution at room temperature, the two benzyl groups of (37) are magnetically equivalent; however, in the solid state, X-ray diffraction reveals that one benzyl group is coordinated in a normal  $\eta^1$ -fashion and the other in an  $\eta^2$  mode. Low-temperature NMR-scale reactions of (37) with  $\text{B}(\text{C}_6\text{F}_5)_3$  and  $\text{Ph}_3\text{C}^+\text{B}(\text{C}_6\text{F}_5)_4^-$  indicate the formation of the corresponding cationic complexes.<sup>190</sup> Several of the cyclopentadienyl-phenoxytitanium derivatives have been structurally characterized by single-crystal X-ray diffraction and the Cp(cent)-Ti-O angle in all cases was found to be approximately  $107^\circ$ .<sup>188–190</sup>

The analogous indenyl-phenoxytitanium complexes have recently been reported, and structurally characterized, with the Ind(cent)-Ti-O angle of approximately  $105^\circ$ . Treatment of  $\text{Ti}(\text{NMe}_2)_4$  with one equivalent 2-(inden-3-yl)-4,6-di-*tert*-butylphenol and its 1,2-di-Me, 2,4,7-tri-Me, and 1,2,4,7-tetra-Me derivatives gives the corresponding bis(dialkylamido) complexes such as,  $[\text{Ti}(\eta^1\text{-OC}_6\text{H}_2\{\eta^5\text{-Ind}\}\text{-2-Bu'}_2\text{-4,6})(\text{NMe}_2)_2]$ .<sup>191</sup> Thermolysis of  $[\eta^5\text{-C}_5\text{H}_4\text{CMe}_2\text{-2-C}_6\text{H}_4\text{OCH}_3]\text{TiCl}_3$  gives  $[\eta^5\text{-}\eta^1\text{-C}_5\text{H}_4\text{CMe}_2\text{-2-C}_6\text{H}_4\text{O}]\text{TiCl}_2$  which is analogous to 37 with a  $\text{CMe}_2$  group between the Cp ring and the phenoxide.<sup>192</sup>

A variety of carborane (*see Carborane*)-appended cyclopentadienyl constrained geometry complexes have been prepared.  $[\eta^5\text{-}\eta^1\text{-Me}_2\text{Si}(\text{C}_5\text{Me}_4)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{TiCl}_2$  was prepared via salt metathesis and amine elimination reactions utilizing the linked *o*-carboranyl ligand,  $\text{Me}_2\text{Si}(\text{C}_5\text{Me}_4\text{H})(\text{C}_2\text{B}_{10}\text{H}_{11})$ .<sup>193</sup>  $\text{Me}_2\text{C}(\text{C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{10})[\text{Ti}(\text{NR}_2)_2 \text{Me}_2\text{Si}(\text{C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{Ti}(\text{NR}_2)_2$  ( $\text{R} = \text{Me}, \text{Et}$ ), were prepared in good yield via amine elimination reactions of  $\text{Ti}(\text{NMe}_2)_4$  and the corresponding neutral ligands in toluene. Treatment of  $[\eta^5\text{-}\sigma\text{-Me}_2\text{C}(\text{C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{Ti}(\text{NMe}_2)_2$  with excess  $\text{Me}_3\text{SiCl}$  gives  $[\eta^5\text{-}\sigma\text{-Me}_2\text{C}(\text{C}_5\text{H}_4)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{TiCl}(\text{NMe}_2)$ .<sup>194</sup> Treatment of  $\text{Ti}(\text{NMe}_2)_4$  with carboranyl-thiol-appended cyclopentadiene ligand, 1-SH-2-[HCpCH(Ph)]-closo-1,2- $\text{C}_2\text{B}_{10}\text{H}_{10}$ , gives the corresponding Ti complex  $[1-(\sigma\text{-S})\text{-2-(}\eta^5\text{-C}_5\text{H}_4\text{CH(Ph)-1,2-C}_2\text{B}_{10}\text{H}_{10})]\text{Ti}(\text{NMe}_2)_2$ , which undergoes

exclusively monohalogenation at titanium with  $\text{Me}_3\text{SiCl}$  or  $\text{Me}_3\text{NHCl}$ , giving  $[1-(\sigma\text{-S})\text{-2-(}\eta^5\text{-C}_5\text{H}_4\text{CH(Ph)-1,2-C}_2\text{B}_{10}\text{H}_{10})]\text{TiCl}(\text{NMe}_2)$  in 71% yield.<sup>195</sup> Treatment of  $\text{Ti}(\text{NMe}_2)_4$  with 1 equivalent of  $i\text{-Pr}_2\text{NB}(\text{C}_9\text{H}_7)(\text{C}_2\text{B}_{10}\text{H}_{11})$ , gives deborated product  $(\eta^5\text{-C}_2\text{B}_9\text{H}_{11})\text{Ti}(\text{NMe}_2)_2(\text{HNMe}_2)$ . Salt metathesis reaction between  $\text{TiCl}_4(\text{THF})_2$  and  $\text{Li}_2[i\text{-Pr}_2\text{NB}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{10})](\text{Et}_2\text{O})_2$  afforded  $[\eta^5\text{-}\sigma\text{-}i\text{-Pr}_2\text{NB}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{TiCl}_2$ . Alternatively,  $[\eta^5\text{-}\sigma\text{-}i\text{-Pr}_2\text{NB}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{10})]\text{TiCl}_2$  was also prepared by the treatment of  $\text{TiCl}_3(\text{THF})_3$  with one equivalent of  $\text{Li}_2[i\text{-Pr}_2\text{NB}(\text{C}_9\text{H}_6)(\text{C}_2\text{B}_{10}\text{H}_{10})](\text{Et}_2\text{O})_2$  followed by addition of 0.5 equivalent of  $\text{PbCl}_2$  in THF.<sup>196</sup> In an analogous manner, treatment of  $\text{Ti}(\text{NMe}_2)_4$  with a series of nido-7,8- $(\text{NMe}_2\text{CH}_2)_2\text{-7,8-C}_2\text{B}_9\text{H}_{11}$  dicarbollide ligands gives mono- and trimetallic titanium complexes  $[\eta^5\text{-}\eta^1\text{-(NMe}_2\text{CH}_2)_2\text{C}_2\text{B}_9\text{H}_9\text{CH}_2\text{NMe}_2]\text{Ti}(\text{NMe}_2)_2$  and  $[\eta^5\text{-}\eta^1\text{-(NMe}_2\text{CH}_2)_2\text{C}_2\text{B}_9\text{H}_9\text{CH}_2\text{NMe}_2]\text{Ti}(\text{NMe}_2)_2(\mu_3\text{-O})[\text{Ti}(\text{NMe}_2)_2]$ .<sup>197</sup>

Constrained geometry titanium complexes with cyclopentadienyl derivatives bridged to the Ti via a Si-N linkage have been prepared and extensively studied as precursors to Ziegler-Natta type polymerization catalysts. Treatment of  $(\eta^5\text{-C}_5\text{H}_4\text{SiMe}_2\text{Cl})\text{TiCl}_3$  with primary aryl amines  $\text{H}_2\text{NR}$  ( $\text{R} = \text{C}_6\text{H}_5, 2,6\text{-Me}_2\text{C}_6\text{H}_3, 2\text{-Me-6-}i\text{-Pr-C}_6\text{H}_3$ ) gives the constrained geometry derivatives  $(\eta^5\text{-}\eta^1\text{-C}_5\text{H}_4\text{SiMe}_2\text{NR})\text{TiCl}_2$ .  $(\eta^5\text{-}\eta^1\text{-C}_5\text{H}_4\text{SiMe}_2\text{N-2,6-Me}_2\text{C}_6\text{H}_3)\text{TiCl}_2$  is converted to  $(\eta^5\text{-}\eta^1\text{-C}_5\text{H}_4\text{SiMe}_2\text{N-2,6-Me}_2\text{C}_6\text{H}_3)\text{TiR}_2$  ( $\text{R} = \text{Me}, \text{CH}_2\text{Ph}, \text{CH}_2\text{SiMe}_3, \text{NMe}_2$ ), by treatment with the appropriate Grignard or organolithium reagents.<sup>198</sup> Marks and coworkers have reported that the treatment of constrained geometry precursors such as  $\text{C}_5\text{H}_5\text{Si}(\text{Me}_2)\text{NHCMe}_3$  with  $n\text{-BuLi}$  to give the dianion followed treatment with  $\text{TiCl}_3\text{THF}_3$ , oxidation with  $\text{PbCl}_2$  and alkylation with  $\text{MeLi}$  to give  $\text{Me}_2\text{Si}(\eta^5\text{-Me}_4\text{C}_5)(t\text{-BuN})\text{TiMe}_2$ , is time consuming and leads to only poor yields. However, they found that treatment of  $\text{C}_5\text{H}_5\text{Si}(\text{Me}_2)\text{NHCMe}_3$  with  $\text{Ti}(\text{CH}_2\text{Ph})_4$  in aromatic or saturated hydrocarbon solvents at  $60^\circ$  gives  $\text{Me}_2\text{Si}(\eta^5\text{-Me}_4\text{C}_5)(t\text{-BuN})\text{Ti}(\text{CH}_2\text{Ph})_2$ , in 90% isolated yield in 12 h.<sup>199</sup> Treatment of  $(\eta^5\text{-}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{NR}')\text{Ti}(\text{CH}_2\text{Ph})_2$  ( $\text{R}' = \text{Me}, i\text{-Pr}, t\text{-Bu}$ ) with  $\text{B}(\text{C}_6\text{F}_5)_3$  or  $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$  in bromobenzene gives the corresponding cationic monbenzyl complex  $[(\eta^5\text{-}\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{NR}')\text{Ti}(\text{CH}_2\text{Ph})]^+$ . Solution NMR studies suggest that the benzyl titanium cations contain a fluxional  $\eta^2$ -coordinated benzyl ligand.<sup>200</sup>

A series of heteroatom substituted indenyl constrained geometry complexes  $[(\eta^5\text{-C}_9\text{H}_5\text{X})(\text{SiMe}_2\text{-}t\text{-Bu})\text{TiR}_2]$  ( $\text{X} = 2\text{-OEt}, 2\text{-NMe}_2, 3\text{-OMe}, 3\text{-NC}_4\text{H}_4$ ;  $\text{R} = \text{Cl}, \text{Me}$ ) were prepared in moderate yield by treatment of the dilithium salt of the ligand with  $\text{TiCl}_3\text{THF}_3$  in THF followed by treatment with  $\text{PbCl}_2$ .<sup>201</sup>

Reactions of  $[\text{Ti}(\eta^5\text{-C}_5\text{Me}_4\text{SiMeXCl})\text{Cl}_3]$  with two equiv. of  $\text{LiNH-}t\text{-Bu}$  afforded the *ansa*-silyl- $\eta$ -amido compounds  $(\eta^5\text{-}\eta^1\text{-C}_5\text{Me}_4\text{SiMeX-N-}t\text{-Bu})\text{TiCl}_2$  ( $\text{X} = \text{H}, \text{Cl}$ ). Methylation of  $(\eta^5\text{-}\eta^1\text{-C}_5\text{Me}_4\text{SiMeX-N-}t\text{-Bu})\text{TiCl}_2$  with  $\text{MgClMe}$  gives

$(\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMeX-N-}t\text{-Bu})\text{TiMe}_2$ .<sup>100</sup> Treatment of  $(\eta^5\text{-1,3-}t\text{-Bu}_2\text{C}_5\text{H}_3)(\eta^5\text{-C}_5\text{H}_4\text{SiClMe}_2)\text{TiCl}_2$ , with two equiv. of  $\text{LiNH-}t\text{-Bu}$  in toluene at  $50\text{--}60^\circ$  gives  $(\eta^5\text{-1,3-}t\text{-Bu}_2\text{C}_5\text{H}_3)(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{SiMe}_2\text{N-}t\text{-Bu})\text{TiCl}$ .<sup>99</sup>

Treatment of  $\{\eta^5:\eta^1\text{-C}_5\text{R}_4\text{SiMe}_2\text{N-}t\text{-Bu}\}\text{TiMe}_2$  ( $\text{R} = \text{H, Me}$ ) with  $\text{HOCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2$  gives a mixture of  $\{\eta^5\text{-C}_5\text{R}_4\text{SiMe}_2\text{NH-}t\text{-Bu}\}\text{TiMe}_2(\text{OCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2)$  and  $\{\eta^5:\eta^1\text{-C}_5\text{R}_4\text{SiMe}_2\text{N-}t\text{-Bu}\}\text{TiMe}(\text{OCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2)$ . Treatment of a mixture of  $\{\eta^5\text{-C}_5\text{R}_4\text{SiMe}_2\text{NH-}t\text{-Bu}\}\text{TiMe}_2(\text{OCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2)$  and  $\{\eta^5:\eta^1\text{-C}_5\text{R}_4\text{SiMe}_2\text{N-}t\text{-Bu}\}\text{TiMe}(\text{OCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2)$  with  $\text{B}(\text{C}_6\text{F}_5)_3$  gives the chelated olefin complexes  $[\{\eta^5:\eta^1\text{-C}_5\text{R}_4\text{SiMe}_2\text{N-}t\text{-Bu}\}\text{Ti}(\text{R}')(\text{olefin})]^+$  intermediates in constrained geometry Ti-catalyzed olefin polymerization. A similar reaction with  $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$  yields  $[\{\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{N-}t\text{-Bu}\}\text{Ti}(\text{OCMe}_2\text{CH}_2\text{CH}_2\text{CH=CH}_2)][\text{B}(\text{C}_6\text{F}_5)_4]$ .<sup>202</sup>

Treatment of  $\text{TiCl}_4$  with  $\text{Li}[(\text{C}_5\text{H}_4)\text{CMe}_2\text{NMe}_2]$  followed by treatment with  $\text{CH}_3\text{Li}$  gives  $[\text{CpCMe}_2\text{NMe}_2]\text{Ti}(\text{CH}_3)_2$ . The reaction of  $[\text{CpCMe}_2\text{NMe}_2]\text{Ti}(\text{CH}_3)_2$  with  $\text{B}(\text{C}_6\text{F}_5)_3$  gives a reactive metallocene cation complex that instantaneously undergoes CH activation at a N-CH<sub>3</sub> group to yield the metallacyclic constrained geometry complex (44).<sup>203</sup>

Treatment of  $\text{Ti}(\text{NMe}_2)_4$  with  $(\text{C}_5\text{H}_5)\text{CH}_2(2\text{-C}_4\text{H}_3\text{NH})$  gives  $[(\eta^5:\eta^1\text{-C}_5\text{H}_4)\text{CH}_2(2\text{-C}_4\text{H}_3\text{N})]\text{Ti}(\text{NMe}_2)_2$  via amine elimination. In an analogous manner treatment of  $\text{Ti}(\text{NMe}_2)_4$  with 1,3- and 1,4- $\{\text{CH}_2(2\text{-C}_4\text{H}_3\text{NH})\}_2\text{C}_5\text{H}_4$  gives  $[(\eta^5:\eta^1\text{-}1,3\text{-}\{\text{CH}_2(2\text{-C}_4\text{H}_3\text{N})\}_2(\eta^5\text{-C}_5\text{H}_3))\text{TiNMe}_2]$ .<sup>204</sup>

Reduction of  $(\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{NR})\text{TiCl}_2$  ( $\text{R} = t\text{-Bu, Ph}$ ) with  $\text{BuLi}$  in the presence of various 1,3-dienes gives the unique constrained geometry diene complexes,  $(\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{NR})\text{Ti}(\text{diene})$  complexes (45). The diene coordination mode ( $\pi$ , formally  $\text{Ti(II)}$ , or metallacyclic, formally  $\text{Ti(IV)}$ ) and the activity for olefin polymerization are highly sensitive to the identity of  $\text{R}$ .<sup>205</sup> Treatment of  $(\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{NR})\text{TiCl}_2$  ( $\text{R} = t\text{-Bu, CHMe(1-C}_{10}\text{H}_7)$ ) with butadienemagnesium gives butadiene complexes analogous to (39) in good yield. The isomer which has the s-cis-butadiene ligand oriented with its open side toward the amido group (prone) is favored.<sup>206</sup>

Treatment of  $\text{Ti}(\text{NMe}_2)_4$  with  $\text{C}_5\text{H}_5\text{B}(\text{NR}_2)\text{NPh}$  ( $\text{R} = i\text{-Pr, SiMe}_3$ ) and  $\text{C}_9\text{H}_7\text{B}(\text{N-}i\text{-Pr}_2)\text{NPh}$  gives the

boron–nitrogen bridged constrained geometry titanium complexes  $(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{B}(\text{NR}_2)\text{NPh})\text{Ti}(\text{NMe}_2)_2$  and  $(\eta^5:\eta^1\text{-C}_9\text{H}_6\text{B}(\text{N-}i\text{-Pr}_2)\text{NPh})\text{Ti}(\text{NMe}_2)_2$  in good yields via the amine elimination reaction. Subsequent deamination-chlorination with excess  $\text{Me}_3\text{SiCl}$  gives the corresponding dichloro complexes  $(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{B}(\text{NR}_2)\text{NPh})\text{TiCl}_2$  and  $(\eta^5:\eta^1\text{-C}_9\text{H}_6\text{B}(\text{N-}i\text{-Pr}_2)\text{NPh})\text{TiCl}_2$ , respectively. Reaction of the analogous ligand precursors containing more bulky  $\text{R}$  groups at nitrogen  $\text{C}_5\text{H}_5\text{B}(\text{N-}i\text{-Pr}_2)\text{N}(\text{H})\text{R}$  ( $\text{R} = \text{Cy, } t\text{-Bu}$ ) with  $\text{Ti}(\text{NMe}_2)_4$  gives the half-sandwich complexes (see *Half-sandwich Complexes*)  $(\eta^5\text{-C}_5\text{H}_4\text{B}(\text{N-}i\text{-Pr}_2)\text{N}(\text{H})\text{R})\text{Ti}(\text{NMe}_2)_3$  ( $\text{R} = \text{Cy, } t\text{-Bu}$ ) rather than the corresponding bridged complexes.<sup>207</sup>

Treatment of  $\text{Li}_2[\text{C}_5\text{H}_4\text{C}(\text{Me}_2)\text{PR}]$  and  $\text{Li}_2[\text{C}_5\text{H}_4\text{CH}(t\text{-Bu})\text{PR}]$  ( $\text{R} = \text{Cy and Ph}$ ) with  $\text{Cl}_2\text{Ti}(\text{NR}'_2)_2$  ( $\text{R}' = \text{Me, Et}$ ) gives the corresponding constrained geometry complexes  $(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{C}(\text{Me}_2)\text{PR})\text{Ti}(\text{NR}'_2)_2$  and  $(\eta^5:\eta^1\text{-C}_5\text{H}_4\text{CH}(t\text{-Bu})\text{PR})\text{Ti}(\text{NR}'_2)_2$  with a C–P bridge as red oils in good yield.<sup>208</sup> The analogous Si–P bridged complex,  $(\eta^5:\eta^1\text{-C}_5\text{Me}_4\text{SiMe}_2\text{Pcy})\text{Ti}(\text{NMe}_2)_2$ , was prepared moderate yield by treatment of  $\text{Li}_2[\text{C}_5\text{Me}_4\text{SiMe}_2\text{P}(\text{cyclohexyl})]$  with  $\text{Cl}_2\text{Ti}(\text{NMe}_2)_2$ .<sup>209</sup> Treatment of  $(t\text{-BuCpP}(t\text{-Bu})\text{Cl})\text{TiCl}_3$  with  $\text{LiN}(\text{H})\text{-}t\text{-Bu}$  in the presence of  $\text{Et}_3\text{N}$  leads to the formation of the constrained geometry complex  $(\eta^5:\eta^1\text{-}t\text{-BuCpP}(t\text{-Bu})\text{N-}t\text{-Bu})\text{TiCl}_2$  in high yield.<sup>101</sup>

Constrained geometry complexes with other  $\pi$  ligands have also been prepared. Treatment of (4-Dimethylsilyl-*tert*-butylamido)-*N,N*-diisopropyl-1-aminoboratabenzene with two equivalents of  $t\text{-BuLi}$  followed by treatment with  $\text{TiCl}_4$  gives (4-Dimethylsilyl-*tert*-butylamido)-*N,N*-diisopropyl-1-aminoboratabenzene titanium dichloride complexes (46).<sup>210</sup> Treatment of  $\text{TiCl}_3\text{THF}_3$  with dianions (47) at low temperature followed by  $\text{PbCl}_2$  gives the corresponding constrained geometry complexes (48) based on the dimethylcyclohexadienyl and dimethylsilacyclohexadienyl ligands.<sup>211</sup>

### 13 CYCLOHEPTATRIENYL COMPLEXES

Reduction of TiCl<sub>4</sub> in the presence of PMe<sub>3</sub>, Me<sub>2</sub>PCH<sub>2</sub>PMe<sub>2</sub>, and Me<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub> with an excess of cycloheptatriene gives (η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti(PMe<sub>3</sub>)<sub>2</sub>Cl, (η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti(Me<sub>2</sub>PCH<sub>2</sub>PMe<sub>2</sub>)Cl, and (η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti(Me<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub>)Cl, respectively.<sup>212,213</sup>

### 14 CYCLOPENTADIENYL–CYCLOHEPTATRIENYL COMPLEXES

The mixed cyclopentadienyl–cycloheptatrienyl (‘5–7’) titanium complex Cp(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti has been prepared in 33–40% yield by the reduction of CpTiCl<sub>3</sub> with isopropylmagnesium bromide or Mg in the presence of cycloheptatriene.<sup>1</sup> Reduction of Cp<sup>\*</sup>TiCl<sub>3</sub> in THF with Mg in the presence of cycloheptatriene gives Cp<sup>\*</sup>(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti in 68% yield.<sup>214</sup> Titanium ‘5–7’ complexes exhibit sandwich structures (see *Sandwich Compound*) with the five-membered and seven-membered rings nearly parallel to each other.

Metalation of Cp(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti with *n*-butyllithium occurs predominantly at the seven-membered ring (equation 60). Dimetalation of Cp(η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti to give (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>Li)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>Li)Ti(TMEDA)<sub>2</sub> has been achieved in 61% yield by treatment with 2 equiv. of BuLi/TMEDA. The dimetalated complex (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>Li)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>Li)Ti(TMEDA)<sub>2</sub> reacts with a wide range of electrophiles, including MeI, Me<sub>3</sub>SiCl, CO<sub>2</sub>, and R<sub>2</sub>PCl, to give the corresponding disubstituted complexes (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>X)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>X)Ti (X = Me, Me<sub>3</sub>Si, CO<sub>2</sub><sup>−</sup>, Me<sub>2</sub>P, Ph<sub>2</sub>P) in good yield (equation 61).<sup>215</sup>

Rausch and coworkers have extensively studied the use of (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PR<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PR<sub>2</sub>) (R = Me, Ph) complexes

as metalloligands. Reactions between (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti and M(CO)<sub>6</sub> (M = Cr, Mo) in refluxing xylene result in the formation of chelated heterobimetallic complexes, [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti]M(CO)<sub>4</sub> (M = Cr, Mo) in high yields, whereas a reaction between (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti and Fe<sub>2</sub>(CO)<sub>9</sub> under similar conditions gives the nonchelated product [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti][Fe(CO)<sub>4</sub>]<sub>2</sub>. Treatment of bis(1,5-cod) nickel with 2 equiv. of (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti in toluene at room temperature leads to displacement of the cod ligands and formation of [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PMe<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PMe<sub>2</sub>)Ti]<sub>2</sub>Ni in 78% yield.<sup>215</sup>

The metalloligand (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti reacts with a variety of metal carbonyls in refluxing toluene to produce a series of chelated heterobimetallic compounds, including [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti]M(CO)<sub>4</sub> (M = Cr, Mo), [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti](CpCo), and [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti]Fe(CO)<sub>3</sub>. The crystal structure of the hemitoluene solvate of [(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti]Cr(CO)<sub>4</sub> has been determined. The phosphino groups are both on the same side of the molecule and coordinated to the Cr atom (Cr–P(av.) = 2.43(2) Å). The Ti–C(η<sup>7</sup>) and Ti–C(η<sup>5</sup>) distances average 2.19(1) and 2.31(2) Å, respectively, with an observed centroid(C5)–Ti–centroid(C7) angle of 173.5°, compared to a centroid(C5)–Ti–centroid(C7) angle of 175.8° in the parent bisphosphine.<sup>216</sup>

Treatment of Mn<sub>2</sub>(CO)<sub>10</sub> with 2 equiv. of (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti in refluxing toluene results in carbonyl group displacement, metal–metal bond cleavage, and hydrogen abstraction to give HMn(CO)<sub>3</sub>[(η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>PPh<sub>2</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>PPh<sub>2</sub>)Ti] in 57% yield. The Mn atom exhibits a distorted octahedral geometry with *cis* phosphines. The coordination geometry in the titanium complex backbone is relatively unaffected by the coordination of manganese.<sup>217</sup>

Treatment of (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>Li)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>Li)Ti·2TMEDA with two equivalents of dimethyldisulfide, diphenyldisulfide, and diphenyldiselenide and gives (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>SCH<sub>3</sub>)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>SCH<sub>3</sub>)Ti, (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>SPh)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>SPh)Ti, and (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>SePh)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>SePh)Ti, respectively in low yield. The crystal structure of (η<sup>5</sup>-C<sub>5</sub>H<sub>4</sub>SPh)(η<sup>7</sup>-C<sub>7</sub>H<sub>6</sub>SPh)Ti, indicates that the five and seven-membered rings are essentially coplanar, and the two phenylthio substituents are in a trans-orientation.<sup>218</sup>

Treatment of (η<sup>7</sup>-C<sub>7</sub>H<sub>7</sub>)Ti(η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub>) with dithioacetic acid, CH<sub>3</sub>CS<sub>2</sub>H, leads to loss of the cycloheptatrienyl to give (η<sup>5</sup>-C<sub>5</sub>H<sub>5</sub>)Ti(S<sub>2</sub>CCH<sub>3</sub>)<sub>3</sub>.<sup>219</sup>

### 15 CYCLOPENTADIENYL–CYCLOOCTATETRAENE COMPLEXES

Mixed ‘5–8’ titanium complexes have been prepared by reduction of Cp<sup>\*</sup>TiCl<sub>3</sub> and CpTiCl<sub>3</sub> with Mg in THF in the presence of cyclooctatetraene to give Cp<sup>\*</sup>(η<sup>8</sup>-C<sub>8</sub>H<sub>8</sub>)Ti

and  $\text{Cp}(\eta^8\text{-C}_8\text{H}_8)\text{Ti}$  in 31 and 38% yield, respectively. Alternatively, reaction of  $\text{Cp}^*\text{TiCl}_3$  with  $\text{K}_2\text{C}_8\text{H}_8$  in THF gives  $\text{Cp}^*(\eta^8\text{-C}_8\text{H}_8)\text{Ti}$  in 34% yield.<sup>214</sup>

## 16 CYCLOOCTATETRAENE COMPLEXES

Treatment of  $\text{TiCl}_4(\text{THF})_2$  with 2 equiv. of  $\text{Li}_2[\text{C}_8\text{H}_6(\text{SiMe}_3)_2]$  and in THF gives  $[\text{Ti}\{\text{C}_8\text{H}_6(\text{SiMe}_3)_2\}_2]$ . The X-ray structure of  $[\text{Ti}\{\text{C}_8\text{H}_6(\text{SiMe}_3)_2\}_2]$  indicates one ring is  $\eta^8$  bound while the other is less readily classified, being intermediate between the  $\eta^3$  structure found for  $[\text{Zr}\{\text{C}_8\text{H}_6(\text{SiMe}_3)_2\}_2]$  and the  $\eta^4$  structure found in  $\text{Ti}(\text{C}_8\text{H}_8)_2$ . In a variable-temperature solution NMR study on  $[\text{Ti}\{\text{C}_8\text{H}_6(\text{SiMe}_3)_2\}_2]$ , the two rings only become equivalent on the NMR timescale above 328 K.<sup>220</sup> In contrast, treatment of  $\text{TiCl}_3(\text{THF})_3$  with one equivalent of 1,4-bis(trimethylsilyl)cyclooctatetraene dianion ( $\text{COT}''$ ) gives a mixture of  $(\text{COT}'')_2\text{Ti}$ ,  $[(\text{COT}'')\text{Ti}]_2(\mu\text{-Cl})_3$  and  $[\eta^8\text{-1,4-(SiMe}_3)_2\text{C}_8\text{H}_6]\text{Ti}(\mu\text{-Cl})_2(\text{THF})$ .<sup>221</sup>

The reduction of  $[(\eta^8\text{-C}_8\text{H}_8)\text{Ti}(\text{THF})(\mu\text{-Cl})]_2$  with magnesium in the presence of bis(trimethylsilyl)acetylene (BTMSA) gives  $[(\eta^8\text{-C}_8\text{H}_8)\text{Ti}]_2[\mu\text{-}\eta^2\text{:}\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3]$  in high yield. The crystal structure of  $[(\eta^8\text{-C}_8\text{H}_8)\text{Ti}]_2[\mu\text{-}\eta^2\text{:}\eta^2\text{-Me}_3\text{SiC}\equiv\text{CSiMe}_3]$  revealed that BTMSA serves as a four-electron ligand to two equivalent  $(\eta^8\text{-C}_8\text{H}_8)\text{Ti}$  units. The average C–C distance of 1.51 Å in the acetylene ligand is close to that of a  $\text{sp}^3$  carbon–carbon single bond, however, the high thermal stability and a large down-field chemical shift of the acetylenic carbon atoms ( $\delta 292.8$  ppm) suggests unusually high  $\pi$ -back-bonding in the Ti–acetylene bond. In contrast, the reduction of  $[(\eta^8\text{-C}_8\text{H}_8)\text{Ti}(\text{THF})(\mu\text{-Cl})]_2$  by magnesium in the presence of diphenylacetylene gave  $(\eta^8\text{-C}_8\text{H}_8)\text{Ti}(\eta^4\text{-C}_6\text{Ph}_4)$  and hexaphenylbenzene.<sup>222</sup>

## 17 OTHER $\eta^5$ -LIGANDS

Seminal work by Ernst and coworkers has shown that the pentadienyl ligand  $\eta^5\text{-C}_5\text{H}_7$  and its alkylated congeners are versatile ligands, possessing features of both Cp and allyl ligands. Treatment of  $\text{TiCl}_2$ , prepared in situ by the reduction of  $\text{TiCl}_4$  with Mg, with potassium 2,4-dimethylpentadienide gives  $(\eta^5\text{-2,4-Me}_2\text{C}_5\text{H}_5)_2\text{Ti}$  (equation 62). Complexes  $(\eta^5\text{-2,4-}t\text{-Bu}_2\text{C}_5\text{H}_5)_2\text{Ti}$  and  $(\eta^5\text{-2,4-(SiMe}_3)_2\text{C}_5\text{H}_5)_2\text{Ti}$  have been prepared in a similar manner. Somewhat surprisingly, these 14-electron open-sandwich compounds have been found to be low-spin (diamagnetic), whereas  $\text{Cp}_2^*\text{Ti}$  possesses two unpaired electrons.<sup>223</sup> The three bis(pentadienyl) complexes have staggered pentadienyl groups. Addition of CO or phosphines leads to the diamagnetic 16-electron complexes  $(\eta^5\text{-2,4-Me}_2\text{C}_5\text{H}_5)_2\text{TiL}$  ( $\text{L} = \text{CO}$  ( $\nu_{\text{CO}} = 1942\text{ cm}^{-1}$ ),  $\text{PMe}_3$ ,  $\text{PEt}_3$ ,  $\text{P(OMe)}_3$ ,  $\text{PMe}_2\text{Ph}$ ) (equation 63) in which the

pentadienyl ligands are syn eclipsed.  $(\eta^5\text{-C}_5\text{H}_7)_2\text{TiPEt}_3$  can be prepared directly by treatment of 'TiCl<sub>2</sub>' with 2 equiv. of  $[\text{C}_5\text{H}_7]^-$  and 1 equiv. of  $\text{PEt}_3$ .<sup>224</sup>

The bis(6,6-dimethylcyclohexadienyl)titanium bent-sandwich complex  $(\eta^5\text{-6,6-Me}_2\text{C}_6\text{H}_5)_2\text{Ti}$  has been prepared in 50% yield by treatment of  $\text{TiCl}_3(\text{THF})_3$  or  $\text{TiCl}_4(\text{THF})_2$  with 6,6-dimethylcyclohexadienylpotassium ( $\text{K}(\text{dmCh})$ ). Carbonylation of  $(\text{dmCh})_2\text{Ti}$  at 1 atm and 25 °C gives the thermally sensitive cherry-red carbonyl adduct  $(\text{dmCh})_2\text{TiCO}$  ( $\nu_{\text{CO}} = 1904\text{ cm}^{-1}$ ) in 95% yield. The carbonyl complex  $(\text{dmCh})_2\text{TiCO}$  has  $\text{C}_{2v}$  symmetry, with a  $\text{dmCh-Ti-dmCh}$  angle of 155°. Treatment of  $(\text{dmCh})_2\text{Ti}$  with  $\text{PF}_3$ ,  $\text{PMe}_3$ , or  $\text{P(OMe)}_3$  at low temperature in solution leads to adducts; however, the lability of these adducts does not allow direct characterization.<sup>225</sup>

Bis( $\eta^5$ -cyclooctadienyl)Ti complexes form monoadducts with both CO and the cage phosphite  $\text{P(OCH}_2)_3\text{CEt}$ . The 16 electron titanium complexes are diamagnetic, exhibiting broad  $^1\text{H}$  NMR spectra indicating that the phosphite complex undergoes rapid, reversible ligand dissociation. Structural data reveal a high degree of steric crowding in these complexes, while the IR data for the bis( $\eta^5$ -cyclooctadienyl)Ti carbonyl complex indicates that the edge-bridged dienyl ligands are substantially stronger electron donors than typical pentadienyl ligands, comparable to the Cp ligand.<sup>226</sup>

The reactions of  $\text{CpTiCl}_2(\text{PR}_3)_2$  ( $\text{R} = \text{Me, Et}$ ) with 2 equiv. of  $\text{KC}_5\text{H}_7$  or  $\text{K}(2,4\text{-C}_7\text{H}_{11})$  ( $\text{C}_7\text{H}_{11}$  = dimethylpentadienyl) gives the corresponding diamagnetic 16 electron  $\text{Cp}(\text{pendadienyl})\text{TiPR}_3$  complexes. A single-crystal X-ray diffraction study of  $\text{Cp}(\eta^5\text{-2,4-C}_7\text{H}_{11})\text{TiPEt}_3$  revealed that the Ti–C bond lengths for the open dienyl ligand are much shorter than those for the Cp ligand, 2.240(3) versus 2.346(4) Å, indicative of stronger Ti– $\text{C}_7\text{H}_{11}$  bonding. Reaction of  $\text{Cp}(\eta^5\text{-2,4-C}_7\text{H}_{11})\text{TiPEt}_3$  with MeCN leads to loss of the  $\text{PEt}_3$  ligand and coupling to the 2,4- $\text{C}_7\text{H}_{11}$  ligand. Thus, the  $\text{C}_7\text{H}_{11}$  ligand is bound more strongly than the Cp ligand (*see Ligand*), yet more reactive. The phosphine ligands in these complexes are readily replaced by treatment with  $\text{P(OMe)}_3$  or  $\text{P(OEt)}_3$ . Treatment of  $\text{CpTi}(\eta^5\text{-2,4-C}_7\text{H}_{11})(\text{PEt}_3)$  with CO leads to thermally unstable monocarbonyl and dicarbonyl complexes.<sup>227</sup>

Pentadienyl complexes  $[\eta^5\text{-1,3-C}_5\text{H}_3(t\text{-Bu})_2]\text{Ti}(\eta^5\text{-2,4-C}_7\text{H}_{11})(\text{PMe}_3)$ ,  $\text{Ti}[\eta^5\text{-1,3-C}_5\text{H}_3(t\text{-Bu})_2](\eta^5\text{-C}_5\text{H}_7)(\text{PR}_3)$  ( $\text{R} = \text{Me or Et}$ ) and  $[\eta^5\text{-1,3-C}_5\text{H}_3(\text{SiMe}_3)_2]\text{Ti}(\eta^5\text{-2,4-C}_7\text{H}_{11})(\text{PMe}_3)$  ( $\text{C}_7\text{H}_{11}$  = dimethylpentadienyl) containing bulky Cp ligands have been prepared. The X-ray structure of  $[\eta^5\text{-1,3-C}_5\text{H}_3(t\text{-Bu})_2]\text{Ti}(\eta^5\text{-C}_5\text{H}_7)\text{PMe}_3$  revealed a markedly shorter Ti–C bonds for the open dienyl ligand as compared to the cyclic one.<sup>228</sup> Structural data have been obtained for these complexes, and for  $\text{Ti}(\eta^5\text{-2,4-C}_7\text{H}_{11})_2(\text{PEt}_3)$ . The presence of the coordinated phosphines in all cases led to the adoption of the expected syn-eclipsed geometries, with the phosphines

positioned by the open dienyl edges. These phosphine ligands cause substantial alterations of the bonding patterns in these species, relative to ligand-free complexes. Most notably, the shortest M–C distances involve the central dienyl carbon atoms.<sup>229</sup>

## 18 ALKOXIDES AND RELATED COMPLEXES

Rothwell and Wolczanski have developed considerable titanium organometallic chemistry utilizing sterically hindered alkoxides as ancillary ligands.

Wolczanski and coworkers have shown that the tritox ligand *t*-Bu<sub>3</sub>CO, with a cone angle (*see Cone Angle*) of 125°, which is slightly smaller than the 136° cone angle for Cp, can serve to sterically ‘saturate’ titanium and allow the development of considerable organometallic chemistry. Reaction of 2 equiv. of Li(tritox) with TiCl<sub>3</sub> gives ‘(tritox)<sub>2</sub>TiCl’, which appears to be monomeric, in contrast to the Cp analog [Cp<sub>2</sub>TiCl]<sub>2</sub> (equation 64). Treatment of ‘(tritox)<sub>2</sub>TiCl’ with excess CCl<sub>4</sub> gives (tritox)<sub>2</sub>TiCl<sub>2</sub>, which can also be prepared directly, in 51% yield, by reaction of TiCl<sub>4</sub> with 2 equiv. of Li(tritox) (equation 65). Similarly, (tritox)TiCl<sub>3</sub> is prepared in 57% yield by treatment of TiCl<sub>4</sub> with 1 equiv. of Li (tritox) (equation 66).

In a manner analogous to the reactivity of Cp<sub>2</sub>TiCl<sub>2</sub>, treatment of (tritox)<sub>2</sub>TiCl<sub>2</sub> with 2 equiv. of MeLi gives (tritox)<sub>2</sub>TiMe<sub>2</sub> in 76% yield (equation 67). In an analogous manner, treatment of (tritox)TiCl<sub>3</sub> with 3 equiv. of MeLi gives (tritox)TiMe<sub>3</sub> in 60% yield (equation 68). (Tritox)<sub>2</sub>TiMe<sub>2</sub> exhibits high thermal stability, with less than 10% decomposition observed over 2 weeks in a benzene solution at 100 °C.<sup>230</sup>

Reaction of (tritox)<sub>2</sub>TiMe<sub>2</sub> with dry O<sub>2</sub> for 8–30 h gives (tritox)<sub>2</sub>Ti(OMe)<sub>2</sub> in 87% yield. Reaction of (tritox)TiMe<sub>3</sub> with O<sub>2</sub> gives three different methoxide complexes, depending upon the stoichiometry of the reagents (equations 69–71).<sup>231</sup>

Rothwell and coworkers have shown that treatment of Ti(CH<sub>2</sub>Ph)<sub>4</sub> with 2 equiv. of 2,6-di-*t*-butylphenol gives the deep-red complex Ti(2,6-*t*-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>2</sub>(CH<sub>2</sub>Ph)<sub>2</sub> in 25–40% yield (equation 72). Thermolysis of Ti(2,6-*t*-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>2</sub>(CH<sub>2</sub>Ph)<sub>2</sub> at 120 °C in hydrocarbon solvents leads to cyclometalation (*see Cyclometalation*) to give Ti[2,6-(*t*-Bu)(CMe<sub>2</sub>CH<sub>2</sub>)C<sub>6</sub>H<sub>3</sub>O](2,6-*t*-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)(CH<sub>2</sub>Ph) (47) (equation 73). Reaction of Ti(CH<sub>2</sub>SiMe<sub>3</sub>)<sub>4</sub> with 2,6-*t*-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>OH at 25 °C for several days gives no observable reaction; however, warming the reaction mixture to 80 °C affords Ti[2,6-(*t*-Bu)(CMe<sub>2</sub>CH<sub>2</sub>)C<sub>6</sub>H<sub>3</sub>O](2,6-*t*-Bu<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)(CH<sub>2</sub>SiMe<sub>3</sub>).<sup>232</sup> Complexes Ti(2,6-Ph<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>2</sub>R<sub>2</sub> (R = Me, CH<sub>2</sub>SiMe<sub>3</sub>, CH<sub>2</sub>Ph, Ph) and Ti(2,6-Ph<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>3</sub>R (R = Me, CH<sub>2</sub>SiMe<sub>3</sub>) are obtained by treating the corresponding homoleptic (*see Homoleptic Compound*) alkyl TiR<sub>4</sub> with 2,6-diphenylphenol in the proper stoichiometry. X-ray crystallographic analysis of Ti(2,6-Ph<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>2</sub>(Ph)<sub>2</sub> and Ti(2,6-Ph<sub>2</sub>C<sub>6</sub>H<sub>3</sub>O)<sub>3</sub>(CH<sub>2</sub>SiMe<sub>3</sub>) demonstrates that the Ti atoms in these complexes are in a pseudotetrahedral environment with short Ti–O distances (1.794(3)–1.806(2) Å) and large Ti–O–C angles (153–179°).<sup>233</sup>

Mixed (alkyl)(aryl oxide) complexes of (ArO)<sub>2</sub>Ti(CH<sub>2</sub>Ph)<sub>2</sub> (Ar = 2,6-Ph<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, 2,6-*i*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) have been found to undergo migratory insertion (*see Migratory Insertion*) with organic isocyanides to give η<sup>2</sup>-iminoacyl derivatives (equation 74). Reaction of (ArO)<sub>2</sub>Ti(CH<sub>2</sub>Ph)<sub>2</sub> with 2,6-dimethylphenyl isocyanide leads initially to the monoiminoacyl derivative (ArO)<sub>2</sub>Ti(η<sup>2</sup>-2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>N=CCH<sub>2</sub>Ph)(CH<sub>2</sub>

Ph) and finally to the bis-insertion product  $(\text{ArO})_2\text{Ti}(\eta^2\text{-2,6-Me}_2\text{C}_6\text{H}_3\text{N}=\text{CCH}_2\text{Ph})_2$  (equation 75).<sup>234</sup> Mild thermolysis of  $(\text{ArO})_2\text{Ti}(\eta^2\text{-2,6-Me}_2\text{C}_6\text{H}_3\text{N}=\text{CCH}_2\text{Ph})_2$  in hydrocarbon solvents gives the corresponding enediamido complexes (equation 76). Treatment of the alkyl-iminoacyl-aryl oxide complexes with 200–1000 psi of CO forms enamidolate complexes (equation 77).<sup>235</sup>

Ar = 2,6-*i*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; R = CH<sub>2</sub>Ph, R' = Ph, 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, *t*-Bu;  
R'' = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>, *t*-Bu

Ar = 2,6-*i*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>; R = CH<sub>2</sub>Ph, R' = *t*-Bu;

Reduction of  $\text{Ti}(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Cl}_2$  (which can be prepared by the reaction of  $\text{TiCl}_4$  with  $\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{OH}$ )<sup>236</sup> with sodium amalgam at room temperature in the presence of  $\text{EtC}\equiv\text{CEt}$  gives a new titanacyclopentadiene complex in 89–90% yield. Titanacycles supported by aryl oxide ligation undergo fragmentation and isomerization and are more reactive than the corresponding bis(cyclopentadienyl)titanacyclopentadiene complexes, as shown in Scheme 9. Treatment of  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})\text{Ti}(\text{EtC}=\text{CEtCEt}=\text{CEt})$  with 3-hexyne at 110 °C gives hexaethylbenzene catalytically.  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})\text{Ti}(\text{EtC}=\text{CEtCEt}=\text{CEt})$  reacts rapidly with MeCN to produce the corresponding pyridine. Addition of  $\text{PhN}=\text{CMeCMe}=\text{NPh}$  or azobenzene to  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})\text{Ti}(\text{EtC}=\text{CEtCEt}=\text{CEt})$  gives the corresponding enediamido complexes  $(\text{RO})_2\text{Ti}(\text{PhNCMe}=\text{CMeNPh})$  and  $(\text{RO})_2\text{Ti}(\text{PhNCEt}=\text{CEtNPh})$ , respectively.<sup>237</sup> Exposure of  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})\text{Ti}(\text{EtC}=\text{CEtCEt}=\text{CEt})$  to ethylene in solution leads rapidly to the formation of the saturated titanacyclopentane  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2)$  and 1,2,5,6-tetraethyl-1,3-cyclohexadiene, as shown in Scheme 10.<sup>238</sup>

Scheme 9

R = Me, Et

Scheme 10

Treatment  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})\text{Ti}(\text{EtC}=\text{CEtCEt}=\text{CEt})$  with olefins gives a variety of stable titanacyclopentane derivatives and one equivalent of substituted 1,3-cyclohexadiene. Reduction of the  $(\text{O-2,6-Ph}_2\text{C}_6\text{H}_3)_2\text{TiCl}_2$  or  $(\text{O-2,3,5,6-Ph}_4\text{C}_6\text{H})_2\text{TiCl}_2$  with Na amalgam (2 Na per Ti) or 2 equiv. of BuLi in the presence of an olefin give the corresponding titanacyclopentane derivatives. These titanacyclopentane complexes undergo facile fragmentation. Addition of phosphine donor ligands gives  $(\text{O-2,6-Ph}_2\text{C}_6\text{H}_3)_2\text{Ti}(\eta^2\text{-CHR}=\text{CH}_2)(\text{L})$  (R = H, Me, Et, Ph,) along with 1 equiv. of free olefin. Addition of  $\text{Ph}_2\text{C}=\text{O}$  or  $\text{PhCH}=\text{NR}$  (R = Ph, CH<sub>2</sub>Ph) to the titanacyclopentane and leads to different products depending upon the reagent and reaction conditions.<sup>239</sup>

Treatment of a hydrocarbon solution of  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\text{CH}_2)_4$  with  $\text{PMe}_3$  leads to the formation of the deep-purple  $\eta^2$ -ethylene complex  $(\text{2,6-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\eta^2\text{-C}_2\text{H}_2)(\text{PMe}_3)$ . A single-crystal X-ray diffraction analysis

of  $(2,6\text{-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\eta^2\text{-C}_2\text{H}_2)(\text{PMe}_3)$  shows a pseudotetrahedral environment about the titanium center with the ethylene aligned perpendicular to the O–Ti–O plane. The Ti–C (ethylene) distances of 2.110 (2) and 2.148 (2) Å, as well as a C–C distance of 1.425 (3) Å, are consistent with a titanacyclopentane bonding description. Addition of  $\text{Ph}_2\text{CO}$  to  $(2,6\text{-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\eta^2\text{-C}_2\text{H}_2)(\text{PMe}_3)$  gives initially the oxatitanacyclopentane complex  $(2,6\text{-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\text{OCPh}_2\text{CH}_2\text{CH}_2)$ , which upon addition of a second equivalent of  $\text{Ph}_2\text{CO}$  gives the dioxametallacyclic complex  $(2,6\text{-Ph}_2\text{C}_6\text{H}_3\text{O})_2\text{Ti}(\text{OCPh}_2\text{CH}_2\text{CH}_2\text{CPh}_2\text{O})$ , as shown in Scheme 11.<sup>240</sup>

$\text{CpTiCl}_2\text{X}$  complexes where X is a OAr, SAR, or carbazole have been prepared. Treatment of  $\text{CpTi}(\text{OAr})\text{Cl}_2$  and  $\text{Cp}^*\text{Ti}(\text{OAr})\text{Cl}_2$  where OAr is a bulky phenol derivative, with 2 equiv. of  $\text{LiMe}$  gives  $\text{CpTi}(\text{OAr})\text{Me}_2$  and  $\text{Cp}^*\text{Ti}(\text{OAr})\text{Me}_2$ , respectively. Alternatively, treatment of  $\text{CpTiMe}_3$  in a cold ether solution of a bulky phenol gives  $\text{CpTi}(\text{OAr})\text{Me}_2$ . Reaction of  $\text{CpTiMe}_3$  with 2 equiv. of less bulky phenol derivatives,  $\text{HOAr}'$  ( $\text{Ar}' = 2,6\text{-dimethyl-phenyl}, 2,6\text{-dimethyl-4-Br-phenyl}$ ), gives  $[\text{CpTi}(\text{OAr}')_2\text{Me}]$ . Reaction of the  $\text{CpTi}(\text{OAr})\text{Me}_2$  with  $[\text{B}(\text{C}_6\text{F}_5)_3]$  generates the corresponding cationic complex,  $[\text{CpTi}(\text{OAr})\text{Me}][\text{MeB}(\text{C}_6\text{F}_5)_3]$ . The thermally unstable cationic readily eliminates methane at room temperature giving  $\text{CpTi}(\text{OAr})(\text{C}_6\text{F}_5)(\text{CH}_2\text{B}(\text{C}_6\text{F}_5)_2)$ . The solid-state structure of  $\text{CpTi}(\text{OC}_6\text{H-2,6-Ph}_2\text{-3,5-Me}_2)(\text{C}_6\text{F}_5)(\text{CH}_2\text{B}(\text{C}_6\text{F}_5)_2)$  confirms the transfer on one  $\text{C}_6\text{F}_5$  to titanium and no interaction of the trigonal-planar boron atom with the adjacent Ti– $\text{C}_6\text{F}_5$  group.<sup>241</sup>

Treatment of  $\text{CpTiCl}_3$  with 1 equiv. of substituted arylsulfide ligands ( $\text{SAr} = 4\text{-Me-SC}_6\text{H}_4, 2,4,6\text{-Me}_3\text{-SC}_6\text{H}_2, 2,4,6\text{-i-Pr}_3\text{-SC}_6\text{H}_2, 2,4,6\text{-Ph}_3\text{-SC}_6\text{H}_2$ ) in benzene gives  $\text{CpTi}(\text{SAr})\text{Cl}_2$ . One electron reduction of  $\text{CpTi}(\text{SAr})\text{Cl}_2$  with  $\text{Na/Hg}$  gives the sulfur-bridged dimers,  $[\text{CpTiCl}(\mu\text{-SAr})]_2$  ( $\text{SAr} = 2,4,6\text{-Me}_3\text{-SC}_6\text{H}_2, 2,4,6\text{-i-Pr}_3\text{-SC}_6\text{H}_2, 2,4,6\text{-Ph}_3\text{-SC}_6\text{H}_2$ ). The solid-state structures of these dimers show that the cyclopentadienyl rings are arranged in a transoid fashion about the  $\text{Ti}(\mu\text{-SAr})_2\text{Ti}$  core.<sup>242</sup> The reaction of  $\text{CpTiCl}_3$  with K carbazolate (Kcb) gives  $\text{CpTi}(\text{cb})\text{Cl}_2$  which can readily be converted  $\text{CpTi}(\text{cb})\text{Me}_2$ .<sup>243</sup>

Scheme 11

Reduction of  $\text{CpTi}(\text{OAr})\text{Cl}_2$  ( $\text{OAr} = 2,3,5,6\text{-tetraphenyl-phenoxide}$ ) with 2 equivalent of sodium amalgam at room temperature in the presence of  $\text{Me}_3\text{C}\equiv\text{CH}$  gives the 2,5-di(*t*-butyl)titanacyclopentadiene complex,  $\text{Cp}(\text{ArO})\text{Ti}(2,5\text{-}t\text{-Bu}_2\text{-C}_4\text{H}_2)$ . When  $\text{Cp}(\text{ArO})\text{Ti}(2,5\text{-}t\text{-Bu}_2\text{-C}_4\text{H}_2)$  is heated at  $100^\circ\text{C}$  for a few days in  $\text{C}_6\text{D}_6$  it isomerizes to the more stable 2,4-di(*t*-butyl) regioisomer.<sup>244</sup>

Treatment of  $[\text{Ti}(\text{CH}_2\text{Ph})_4]$  with carbazole gives  $\text{Ti}(\text{cb})_2(\text{CH}_2\text{Ph})_2$ .  $\text{Ti}(\text{cb})_2(\text{CH}_2\text{Ph})_2$  reacts with 2,6-dimethylphenyl isocyanide to generate the corresponding bis(iminoacyl) derivative, in which the iminoacyl is  $\eta^2\text{-C,N}$  binding. The reaction of the more bulky  $[\text{Ti}(\text{CH}_2\text{SiMe}_3)_4]$  with cbH at  $100^\circ\text{C}$  gives the alkylidene bridged dimer  $[(\text{cb})_2\text{Ti}(\mu\text{-CHSiMe}_3)_2\text{Ti}(\text{cb})_2]$  which was structurally characterized. The reaction of  $\text{CpTiCl}_3$  with K carbazolate (Kcb) gives  $\text{CpTi}(\text{cb})\text{Cl}_2$  which can readily be converted  $\text{CpTi}(\text{cb})\text{Me}_2$ .<sup>243</sup>

Treatment of  $(2,6\text{-Ph}_2\text{-3,5-Me}_2\text{C}_6\text{HO})_2\text{Ti}(\text{CH}_2\text{Ph})_2$  with  $[\text{B}(\text{C}_6\text{F}_5)_3]$  gives the corresponding zwitterionic species  $(2,6\text{-Ph}_2\text{-3,5-Me}_2\text{-C}_6\text{HO})_2\text{Ti}(\text{CH}_2\text{Ph})[\eta^6\text{-C}_6\text{H}_5\text{CH}_2\text{B}(\text{C}_6\text{F}_5)_3]$ <sup>245</sup>

## 1 INTRODUCTION

Metal carbonyl compounds are, with very few exceptions, polyatomic molecules with, as might be expected, rich and interesting infrared spectra. For a molecule  $\text{M}(\text{CO})_x(\text{L})_y$ , there will be absorptions due to the motions of the CO groups and, of course, any other ligands attached to the metal. It might seem a little myopic then to concentrate by far the greatest proportion of spectroscopic effort to the region around  $2000\text{ cm}^{-1}$ . Around this  $2000\text{ cm}^{-1}$  region of the IR (and Raman) spectrum, we find the ‘CO-stretching’ bands,  $\nu(\text{CO})$ , of metal carbonyl complexes. The number, pattern, and position of these absorptions give an enormous amount of information about molecular structure, symmetry, and bonding. The ‘ $\nu(\text{CO})$ ’ region has, since the early 1960s, been the scene of some exciting work and the arena for many arguments.

In the mid-1970s, Brateman<sup>1</sup> published a complete text devoted to metal carbonyl spectra and, although out of date in several areas, it remains a valuable resource, particularly in its advice on sample preparation and handling where the generally high toxicity and ready decomposition of metal carbonyl complexes causes more problems than might be usually found. Another helpful source of information, although even older, by Adams<sup>2</sup> contains  $\nu(\text{CO})$  information on a large number of transition metal carbonyl complexes.

Paradoxically, gaseous carbon monoxide itself is not a strong IR absorber. Yet the IR spectrum of any transition metal carbonyl complex with terminal CO groups is dominated by the very high intensity of some of the CO-stretching absorptions. Since IR intensities are proportional to the square of the dipole change associated with the vibration, the implication is that there is a large dipole change when a carbonyl group vibrates. This effect derives from the  $\pi$ -bonding in the M–C–O unit.<sup>3</sup> The stretching of a CO group bonded to a metal atom leads to a lowering of the energy of the  $2\pi$  orbital, since the antibonding interaction is weakened and the orbital becomes a better acceptor. At the same time, the overlap of the carbon and the metal orbitals is increased as the M–C distance lessens. There is, therefore, a great deal of electronic flow and ebb within each vibration and, consequently, a high dipole change.

## 2 PRINCIPLES OF MOLECULAR FORCE FIELDS

The bonds that hold molecules together obey Hooke’s law (for small distortions at least). That is, the restoring force  $F$  is proportional to the extension  $x$

$$F = -kx \quad (1)$$

The potential energy,  $V$ , of such a system is given by

$$V = \frac{(kx^2)}{2} \quad (2)$$

The constant of proportionality ( $k$ ) in both cases is the stretching force constant and, in the same way that a force constant can measure the strength of a mechanical spring,  $k$  gives a measure of the strength of a chemical bond. Indeed, the force constant measures bond strength when the atoms are near their equilibrium positions, a far more subtle measure than the dissociation energy.

The vibration of a molecule does not affect its center of mass. The vibration is equivalent to that of a single particle of reduced mass  $\mu$  moving in a field of force constant  $k$ . A diatomic molecule AB (such as CO) will vibrate with a frequency  $\nu_{AB}$  given by the equation

$$\nu_{AB} = \frac{1}{2\pi} \sqrt{\frac{k_{AB}}{\mu_{AB}}} \quad (3)$$

where  $\mu_{AB}$  is the reduced mass of the molecule, given by

$$\mu_{AB} = \frac{(m_A \times m_B)}{(m_A + m_B)} \quad (4)$$

Rearranging equations (3) and (4), and gathering constants so that  $\nu_{AB}$  is in  $\text{cm}^{-1}$  and the masses of the atoms are in

atomic mass units, gives  $k_{AB}$  in SI units of newtons per meter ( $\text{N m}^{-1}$ ):

$$k_{AB} = 5.8915 \times 10^{-5} \nu_{AB}^2 \mu_{AB} \quad (5)$$

If the atoms concerned are  $^{12}\text{C}$  and  $^{16}\text{O}$ , then

$$k_{\text{CO}} = 4.0393 \times 10^{-4} \nu_{\text{CO}}^2 \quad (6)$$

Clearly, calculating the force constant of a diatomic molecule is simple if we know its vibrational frequency.

Unfortunately, the finding of a set of force constants for a polyatomic molecule is greatly complicated by the fact that distorting one bond will affect all the other bonds in the molecule to some extent. A rigorous description of the problem of finding force constants from frequencies (and *vice versa*) in polyatomic molecules has been given by Wilson, Decius, and Cross.<sup>4</sup> Here a simpler, almost qualitative approach, is presented.

Equation (5) could have been written as

$$k_{AB} \mu_{AB}^{-1} - 5.8915 \times 10^{-5} \nu_{AB}^2 = 0$$

or, more conveniently,

$$k_{AB} \mu_{AB}^{-1} - \lambda_{AB} = 0 \quad (7)$$

If the bonds in a polyatomic molecule were to vibrate in total isolation (i.e., without affecting any other bonds in the molecule), there would be a series of equations similar to equation (7):

$$\begin{aligned} k_1 \mu_1^{-1} - \lambda_1 &= 0 \\ k_2 \mu_2^{-1} - \lambda_2 &= 0 \\ k_3 \mu_3^{-1} - \lambda_3 &= 0 \end{aligned} \quad (8)$$

and so on.

Unfortunately, in real molecules the situation is not that simple. Stretching a bond in a polyatomic molecule has consequences for every other bond in the molecule, both in terms of the alteration of orbital energies (and by implication, the strength of the bonds) and the mechanical movement of neighbor atoms. The effects on the orbital energies can be thought of as a matrix containing all the force constants (called the  $F$  matrix). The  $F$  matrix contains **stretching force constants** along the diagonal (e.g.,  $k_1, k_2, k_3$ , etc.) and off-diagonal terms, which are called **interaction constants** ( $k_{12}, k_{13}, k_{23}$ , etc.). Similarly, the matrix with inverse reduced masses (called the  $G$  matrix) contains off-diagonal terms for atoms, which are common between two bonds, although the  $G$  matrix elements linking distortions with no atom in common are zero. Short-circuiting some involved mathematics

then, this reduces our overall problem to a single secular equation:

$$|FG - \lambda E| = 0 \quad (9)$$

The off-diagonal terms in  $\lambda$  have been removed (simply because they do not exist), while the diagonal elements occur with coefficients of unity.

Theoretically then, given the complete structure of a molecule (from which the  $G$  matrix can be constructed) and all the force constants (the force field from which the  $F$  matrix can be constructed), we can calculate the vibrational frequencies. Unfortunately, the problem is nearly always the other way round. We invariably have the observed vibrations and need to calculate force constants. The basic problem with calculating force fields is that a nonlinear molecule of  $N$  atoms has  $3N - 6$  fundamental vibrations and there are  $(N^2 + N)/2$  independent force constants. Clearly then, for substantial transition metal carbonyl molecules, such as *cis*- $\text{Cr}(\text{CO})_4(\text{PF}_3)_2$  for example, there are (even allowing for symmetry) many more force constants than observable fundamental frequencies. So, even in the most sophisticated force fields, approximations will appear in some form or the other. A ‘general quadratic valence force field’ (GQVFF)<sup>5</sup> seeks to use harmonic frequencies and to take account of all terms in the  $F$  and  $G$  matrices. In truth, the GQVFF is the only way to find a ‘real’ solution to equation (9). A general procedure for a GQVFF study is as follows: high-resolution IR and Raman spectra are taken; intensity data are collected; fundamental, combination, and overtone bands are analyzed; and related species are compared to establish trends and aid the assignment of fundamental vibrations. Isotopic substitution is routinely used to give a chemically identical molecule with atoms of different masses (i.e., the  $F$  matrix is unchanged but the  $G$  matrix has different elements). This, hopefully, provides sufficient additional data to ensure that the number of observed frequencies equals or is greater than the number of force constants. After all accessible information has been gathered, it is processed to give a force field. This has, for many years now, been accomplished by computer programs that can optimize a solution to a ‘best fit’ situation and provide some feel for the errors that are present in the measurements. This list of prerequisites for a GQVFF study limits the enthusiasm for undertaking such work. In his study of the group 6 hexacarbonyls ( $\text{Cr}(\text{CO})_6$ ,  $\text{Mo}(\text{CO})_6$ ,  $\text{W}(\text{CO})_6$ ), Jones<sup>6</sup> collected and analyzed IR and Raman spectra of the  $\text{M}(\text{C}^{12}\text{O})_6$  species in the gas phase, cyclohexane or  $\text{CCl}_4$  solution, and as solids. He then repeated the entire process for the  $\text{M}(\text{C}^{12}\text{O})_6$  and  $\text{M}(\text{C}^{13}\text{O})_6$  species. Even then, for  $\text{Cr}(\text{CO})_6$ , a ‘unique solution’ depended on some minor, but still fairly arbitrary, approximations.

Clearly, a method that requires such devotion will only ever attract a small number of protagonists. A different approach has been adopted for metal carbonyls, which arises from an interesting situation.

### 3 ENERGY FACTORED FORCE FIELDS

The vibrational spectra of metal carbonyls have absorptions that involve the M–C–O unit in the regions given in Table 1.

Notice that the  $\nu(\text{CO})$  vibrations are much higher in frequency than all other involving the M–C–O unit. Thus, it is not unreasonable to think of the  $\nu(\text{CO})$  modes as completely C–O stretching. Taking this thought one stage further, we might argue that, while coupling between different  $\nu(\text{CO})$  modes occurs (via off-diagonal terms in the  $F$  matrix), coupling between  $\nu(\text{CO})$  and any other vibration can be neglected. By this process, usually described as energy factoring, we radically reduce the sizes of the  $F$  and  $G$  matrices. In effect, we are blinkered so that we totally ignore every vibration except those assigned as ‘C–O stretching’ modes. In the  $F$  matrix, all terms which link the displacement of a C–O bond to the change in any other bonds (apart from another CO group) are neglected. This means that only two types of force constant remain in the  $F$  matrix: C–O stretching force constants ( $k_{\text{CO}}$ ) along the diagonal, and CO–CO interaction constants ( $k_{\text{CO,CO}}$ ) as off-diagonal terms. The  $G$  matrix is reduced to an array containing the reciprocal mass of the CO group as the only elements (along the diagonal) since no two CO groups have a common atom. For the spectroscopist, a carbonyl such as  $\text{Ni}(\text{CO})_3\text{PF}_3$  might have a rich and interesting spectrum, but in trying to glean some information about the bonding within the molecule, we here would only be interested in the two sharp, intense bands in the  $\nu(\text{CO})$  region.

This approach was first described in detail by Cotton and Kraihanzel in 1962.<sup>7</sup> The *Cotton–Kraihanzel Force Field* (CKFF) was very quickly taken up by workers in the field and extensively used as a tool for analyzing  $\nu(\text{CO})$  frequencies to produce force constants that made chemical sense and were readily accessible. Now, with its application in metal nitrosyl<sup>8</sup> and dinitrogen spectroscopy<sup>9</sup> the CKFF often appears under the more general name of the *Energy Factored Force Field* (EFFF) or *Frequency Factored Force Field* ( $F^4$ ). An equally important paper, by Haas and Sheline,<sup>10</sup> followed Cotton’s pioneering work and investigated the mathematics rather more fully, and facilitated work on isotopic species.

However, the Cotton–Kraihanzel force field and the entire philosophy of energy factoring was sharply criticized by Jones who contended that the CKFF yielded CO force constants, which showed some consistency of pattern but which had no theoretical foundation except in ‘gross approximation’.<sup>5</sup> The validity of the EFFF was further called into question following

the GQVFF study of the group 6 hexacarbonyls.<sup>6</sup> The GQVFF force constants (especially the CO–CO interaction constants) calculated were *very* different from those obtained by using anharmonic frequencies in an EFFF. This meant that the proposal that (in octahedral complexes) the *cis* and *trans* CO–CO interaction constants should be related by:

$$k_{\text{trans}} = 2k_{\text{cis}} \quad (10)$$

was extremely dubious. It remained, however, a useful approximation when there were more EFFF force constants than observable frequencies and, for anharmonic frequencies at least, it seemed to work. For example, the monosubstituted octahedral complexes  $\text{M}(\text{CO})_5\text{L}$  ( $C_{4v}$  point group) have four fundamental  $\nu(\text{CO})$  modes ( $2a_1 + b_2 + e$ ). Unfortunately, there are five force constants, which means that the problem is underdetermined with one degree of freedom. However, this can be removed by using equation (10) and a ‘solution’ can be obtained. If the  $b_2$  mode is not observed (it is, strictly, IR-inactive), Cotton approximated further and reduced all the CO–CO interactions to a single parameter,  $k_i$ :

$$k_{\text{cis}} = \frac{1}{2}k_{\text{trans}} = k_i \quad (11)$$

Confusingly, in the light of Jones’ work,<sup>11</sup> a number of studies by Bor<sup>12</sup> showed that the EFFF was capable of accurately analyzing complicated isotopic spectra. Elsewhere, Turner and coworkers were producing transition metal carbonyl fragments (e.g.,  $\text{Mo}(\text{CO})_5$ ,  $\text{Fe}(\text{CO})_3$ ) in low-temperature matrices and using the EFFF to fit observed frequencies very closely to a set of force constants.<sup>13</sup> Like Bor, they were not using completely substituted species, but the whole range of isotopomers (e.g.,  $\text{Mo}({}^{12}\text{C}^{16}\text{O})_{5-x}({}^{13}\text{C}^{16}\text{O})_x$ ,  $x = 0-5$ ). Remarkably, in view of Jones’ comments, an entire spectrum was regularly being fitted with an average error of less than  $1\text{ cm}^{-1}$  with a unique set of EFFF force constants.

Obviously, there is a dilemma here. Without doubt, the EFFF can be used to fit complicated isotopic spectra with remarkable accuracy, and yet the force constants it uses appear to be at variance with the ‘true’ force constants. If the  $F$  matrix of the EFFF is only a gross approximation of the ‘true’ (viz. GQVFF)  $F$  matrix, then why does the EFFF work so well?

Isotopic substitution in metal carbonyl complexes does not alter the force constant matrix, but changes the elements along the diagonal of the simplified EFFF  $G$  matrix from the inverse reduced mass of  ${}^{12}\text{C}^{16}\text{O}$  to the inverse reduced mass of the isotopic group (most frequently  ${}^{13}\text{C}^{16}\text{O}$ , although  ${}^{12}\text{C}^{18}\text{O}$  was commonly used for earlier studies<sup>14</sup>). Relevant data for the commonly used isotopes in CO is given in Table 2.

When the molecule is completely substituted by isotopically different CO, the  $\nu(\text{CO})$  frequencies of the fully

**Table 1** Vibrations associated with  $\text{M}(\text{CO})_n$  complexes

| Approximate description            | Range ( $\text{cm}^{-1}$ ) |
|------------------------------------|----------------------------|
| C–O stretching $\nu(\text{CO})$    | 2150–1750                  |

| C–M–C bending $\delta(\text{CMC})$ | 150–50                     |

**Table 2** Mass data for  $^x\text{C}^y\text{O}$  ( $x = 12, 13$ ;  $y = 16, 18$ )

|                    | $^{12}\text{C}^{16}\text{O}$ | $^{13}\text{C}^{16}\text{O}$ | $^{12}\text{C}^{18}\text{O}$ | $^{13}\text{C}^{18}\text{O}$ |
|--------------------|------------------------------|------------------------------|------------------------------|------------------------------|
| Reduced mass       | 6.85621                      | 7.17241                      | 7.19987                      | 7.54937                      |
| Reduced mass ratio | 1.00000                      | 0.97771                      | 0.97586                      | 0.95300                      |

substituted molecule should be related to those of the parent (all  $^{12}\text{C}^{16}\text{O}$ ) molecule by

$$\nu' = \left(\frac{\mu}{\mu'}\right)^{\frac{1}{2}} \nu = R\nu \quad (12)$$

where  $\nu$  and  $\nu'$  are the frequencies of the parent and the fully substituted molecule, respectively, and  $\mu$  and  $\mu'$  are the reduced masses of the  $^{12}\text{C}^{16}\text{O}$  and the isotopic CO. The constant  $R$  has been called (somewhat incorrectly) the reduced mass ratio. Unfortunately, equation (12) is not found to be absolutely accurate in practice. When  $^{12}\text{C}^{16}\text{O}$  is replaced by  $^{13}\text{C}^{16}\text{O}$  ( $R = 0.977709$ ), the differences between observed and calculated frequencies are generally low. However, when  $^{12}\text{C}^{18}\text{O}$  ( $R = 0.975855$ ) replaces  $^{12}\text{C}^{16}\text{O}$ , errors of up to  $5\text{ cm}^{-1}$  are commonplace. Bor<sup>15,16</sup> used the idea of an ‘effective reduced mass ratio’, which reduces the error, but this is clearly hiding problems within the EFFF. The double assumptions that anharmonicity (up to  $40\text{ cm}^{-1}$  in some cases) can be neglected and that M–C/C–O coupling is negligible are breaking down.

Burdett *et al.*<sup>17</sup> showed that, to fit isotopic spectra accurately, the EFFF needed two corrections: a factor that takes into account the particular isotope of CO used and a further correction to ameliorate the effects of using anharmonic frequencies. The effect of the neglect of M–C/C–O coupling was originally explained by Miller<sup>18</sup> in terms of an  $x$ -factor, which depended on the particular CO isotope being used. Anharmonicity is accounted for by another correction that could be determined from the all- $^{12}\text{C}^{16}\text{O}$  molecule and the reduced mass ratio.

The effect of these two corrections is best shown (in Table 3) by the close examination of the  $t_{1u}$  mode of various isotopomers of  $\text{Cr}(\text{CO})_6$  in methane matrices at 20 K.

The convincing fit is a considerable improvement on the simplest equation. For other carbonyls and other modes, the dramatic reduction in error is similar. However, it is not possible to apply the  $x$ -shift and the anharmonicity correction unless the GQVFF force field and the anharmonicity corrections are known. That said, some useful generalizations can be outlined:

1. the shift due to anharmonicity is always positive for  $^{13}\text{C}^{16}\text{O}$ ,  $^{12}\text{C}^{18}\text{O}$ , and  $^{13}\text{C}^{18}\text{O}$ ;
2. the  $x$ -factor shift is negative for  $^{13}\text{C}^{16}\text{O}$ , but positive for  $^{12}\text{C}^{18}\text{O}$  and  $^{13}\text{C}^{18}\text{O}$ .

**Table 3** Observed and calculated wavenumbers for the  $t_{1u}\nu(\text{CO})$  mode of  $\text{Cr}(^a\text{C}^b\text{O})_6$  ( $a = 12, 13$ ;  $b = 16, 18$ )

|                                  | $^{12}\text{C}^{16}\text{O}$ | $^{13}\text{C}^{16}\text{O}$ | $^{12}\text{C}^{18}\text{O}$ | $^{13}\text{C}^{18}\text{O}$ |

<sup>a</sup>Used to calculate other frequencies (in methane matrices at 20 K).

The general conclusion from these observations is that  $^{13}\text{C}^{16}\text{O}$  will follow the restrictions of the EFFF best because the shifts caused by anharmonicity and M–C/C–O coupling are of similar magnitude and opposite in sign. We can also see that Bor’s effective reduced mass arises through combining the corrections for M–C/C–O coupling and anharmonicity into a single parameter.

The vibrational frequencies of a fully isotopically substituted carbonyl are more or less related to those of the parent molecule in such a way that no new information about the force field can be learned. The situation is different when molecules are partially substituted;  $\text{Cr}(\text{CO})_6$  is used to illustrate the point.  $\text{Cr}(^{12}\text{C}^{16}\text{O})_6$  has three fundamental C–O stretches:  $a_{1g}$  (Raman),  $e_g$  (Raman), and  $t_{1u}$  (IR). The force constants that are required are a single stretching force constant ( $k_{\text{CO}}$ ), an interaction constant for mutually *cis* CO groups ( $k_{\text{cis}}$ ), and another interaction constant for mutually *trans* CO groups ( $k_{\text{trans}}$ ). There are three absorptions and three fundamentals, so the force field is fully determined. If, instead of the parent molecule, we had  $\text{Cr}(^{12}\text{C}^{16}\text{O})_5(^{13}\text{C}^{16}\text{O})$  we would have a molecule with  $C_{4v}$  symmetry and five fundamental  $\nu(\text{CO})$  bands ( $3a_1 + b_2 + e$ ). With five observed frequencies and only three force constants the force field can be optimized to give a best fit. Access to the entire range of isotopomers in the  $\text{Cr}(^{12}\text{C}^{16}\text{O})_{6-x}(^{13}\text{C}^{16}\text{O})_x$  series would provide many more observable absorptions than force constants. The best fit force field can be defined as that which reproduces a set of frequencies closest to those observed. From the discussion above, a  $^{12}\text{C}^{16}\text{O}/^{13}\text{C}^{16}\text{O}$  mixture would be expected to give low mean errors for  $^{12}\text{C}^{16}\text{O}/^{12}\text{C}^{18}\text{O}$ , with  $^{12}\text{C}^{16}\text{O}/^{13}\text{C}^{18}\text{O}$  giving substantially higher mean errors; this is indeed the case. When Bor’s effective reduced mass is introduced as an additional variable, the errors in  $^{12}\text{C}^{16}\text{O}/^{12}\text{C}^{18}\text{O}$  and  $^{12}\text{C}^{16}\text{O}/^{13}\text{C}^{18}\text{O}$  spectra become comparable with those for  $^{12}\text{C}^{16}\text{O}/^{13}\text{C}^{16}\text{O}$ .

A point to be made here, most forcibly, is that, although the EFFF is an *approximate* force field, it readily produces force constants that are *valid* (in the sense that they provide crucial information about chemical bonding) and *reliable*.

#### 4 CO–CO INTERACTION CONSTANTS

Without a large number of GQVFF studies on carbonyl complexes the actual relationship between EFFF and GQVFF interaction constants will not be resolved. This does not mean, however, that the CO–CO interaction constants are of no value. Indeed, the magnitude of the interaction constant had long been thought of as a strong indicator of  $\pi$ -bonding within M–C–O units;<sup>19</sup> for a large number of tetrahedral  $\text{Ni}(\text{CO})_3(\text{L})$ ,  $\text{Ni}(\text{CO})_2(\text{L})_2$ , and  $\text{Co}(\text{CO})_2(\text{NO})(\text{L})$  complexes there is an excellent linear correlation<sup>20</sup> between the CO-stretching force constant,  $k_{\text{CO}}$ , and the associated CO–CO interaction constant,  $k_i$ :

$$k_i = 203 - 0.983k_{\text{CO}} \quad (13)$$

So, while remaining as an unknown and complex mixture of GQVFF force constants,  $k_i$  must reflect systematic changes in these ‘true’ force constants. Similar straight lines are found for CO groups at  $90^\circ$ ,  $120^\circ$ , and  $180^\circ$ . In summary, if two CO groups (with force constants  $k_1$  and  $k_2$ ) are bonded to a metal atom M, the EFFF interaction constant ( $k_{12}$ ) is given by

$$k_{12} = A - B \left[ \frac{(k_1 + k_2)}{2} \right] \quad (14)$$

where  $A$  and  $B$  are empirical constants (given in Table 4) for a given C–M–C bond angle. The importance of these relationships is that it removes the need for the arbitrary constraints such as those proposed by Cotton<sup>7</sup> and, later, by van der Kelen<sup>21</sup> and it provides an excellent way of removing various degrees of freedom from force fields.

Let us take the simple case of  $\text{Ni}(\text{CO})_4$  to demonstrate the usefulness of equation (14).

A dilute solution of  $\text{Ni}(\text{CO})_4$  in heptane shows a single band at  $2045.7\text{ cm}^{-1}$  in the  $\nu(\text{CO})$  region.<sup>22</sup> This is the  $t_2$  asymmetric stretch. The symmetric stretch ( $a_1$ ) is Raman-active only. The EFFF force constants required for  $\text{Ni}(\text{CO})_4$  are  $k_{\text{CO}}$  and  $k_i$  (the CO-stretching force constant and the CO,CO interaction constant respectively) and it would appear impossible to calculate two force constants from one  $\nu(\text{CO})$  absorption. However, the symmetry force constant for the  $t_2$  mode is

$$K(t_2) = k_{\text{CO}} - k_i \quad (15)$$

**Table 4** Values of  $A$  and  $B$  for common C–M–C bond angles

| Bond angle | $A$ ( $\text{N m}^{-1}$ ) | $B$ (dimensionless) |
|------------|---------------------------|---------------------|
| 90         | 180                       | 0.0929              |
| 109        | 203                       | 0.0983              |
| 120        | 221                       | 0.1115              |
| 180        | 241                       | 0.1134              |

which, using equation (15), can be rewritten as

$$K(t_2) = k_{\text{CO}} - (A - Bk_{\text{CO}}) \quad (16)$$

This can be rearranged to give

$$k_{\text{CO}} = \frac{(K(t_2) + A)}{(1 + B)} \quad (17)$$

from which it can be calculated that  $k_{\text{CO}} = 1723.9\text{ N m}^{-1}$  and  $k_i = 33.6\text{ N m}^{-1}$ , and coincidentally, predicting that the  $a_1$  stretch would occur at  $2125.3\text{ cm}^{-1}$  (observed in the Raman spectrum at  $2125.0\text{ cm}^{-1}$ ).

It is a simple enough matter to extend this to complexes which, even if all the  $\nu(\text{CO})$  absorptions were observed, would still have more force constants than observed frequencies (i.e., underdetermined force fields). As an example, consider the force field (Table 5) of  $\text{HMn}(\text{CO})_5$  isolated in a methane matrix at 20 K which has three IR absorptions and five force constants. The close correspondence between the force constants calculated by different means is quite striking.

Carbonyl anions and cations are found not to obey equation (14) in its most simple form. They can be included in the scheme, however, if the charge is taken into account via a parameter  $C$  (the charge factor) to give the more complete relationship

$$k_{a,b} = A - B \left[ \frac{(k_a + k_b)}{2} - C \right] \quad (18)$$

It is found that  $C$  ( $120\text{ N m}^{-1}$ ) is independent of the structure of the molecule. If a molecule is doubly charged, the correction is  $2C$ . The effect of charges on the force constants of the three  $d^6$  hexacarbonyl species  $\text{V}(\text{CO})_6^-$ ,  $\text{Cr}(\text{CO})_6$  and  $\text{Re}(\text{CO})_6^+$  is illustrated in Table 6.

**Table 5** Energy factored force field for  $\text{HMn}(\text{CO})_5$

|                        | Approx. <sup>a</sup> | Exact <sup>b</sup> |
|------------------------|----------------------|--------------------|
| $k_2$                  | 1656                 | 1652.42            |
| $k_1$                  | 1692                 | 1690.61            |
| $k_{12}$               | 28                   | 32.60              |
| $k_{11(\text{cis})}$   | 23                   | 24.72              |
| $k_{11(\text{trans})}$ | 49                   | 48.27              |

<sup>a</sup>Using equation (14). <sup>b</sup>Best fit values from isotopic spectra. All force constants in  $\text{N m}^{-1}$ .

**Table 6** Force constants of  $d^6$  hexacarbonyls<sup>1</sup>

|                            | $k_{\text{CO}}$ | $k_{\text{cis}}$ | $k_{\text{trans}}$ |
|----------------------------|-----------------|------------------|--------------------|
| $\text{V}(\text{CO})_6^-$  | 1454.9          | 33.2             | 60.4               |
| $\text{Cr}(\text{CO})_6$   | 1644.2          | 26.1             | 53.6               |
| $\text{Re}(\text{CO})_6^+$ | 1809.2          | 21.8             | 53.2               |

In the light of the  $k_{\text{CO}}/k_i$  relationships of table 4. Cotton's durable approximation (equation 10) has been reevaluated and the empirical relationship

$$k_{\text{trans}} = 21.3 + 1.22k_{\text{cis}} \quad (19)$$

has been proposed.<sup>23</sup> This equation agrees very well with Cotton's approximation when  $k_{\text{CO}}$  is in the region of  $1650 \text{ N m}^{-1}$ . Coincidentally, this is almost the same as the force constants for the group 6 hexacarbonyls.

## 5 CALCULATING FORCE CONSTANTS FROM $\nu(\text{CO})$ SPECTRA

### 5.1 Force Constant Nomenclature and Symmetry Considerations

Before describing how force fields may be calculated, let us clarify the nomenclature used. The stretching force constants of a metal carbonyl will be numbered sequentially as  $k_1$ ,  $k_2$ ,  $k_3$  and so on. The CO groups denoted by  $k_1$  will be the most common. The CO,CO interaction constants will refer to the CO groups interacting. Thus,  $k_{11}$  arises in the  $F$  matrix where two  $k_1$  CO groups interact. So, for a molecule such as  $\text{Fe}(\text{CO})_5$  there will be five EFFF force constants:  $k_1$  (for the equatorial CO groups),  $k_2$  (for the axial CO groups) and three interaction constants,  $k_{11}$ ,  $k_{12}$ ,  $k_{22}$ . Even where there is only one type of carbonyl group in the molecule, we will adhere to this convention for the sake of consistency.

We will, throughout this section, refer to 'symmetry force constants' ( $K(\Gamma)$  where  $\Gamma$  is the symmetry of the vibrational mode) derived directly from observed frequencies. Since we will be dealing with all- $^{12}\text{C}^{16}\text{O}$  molecules as a matter of course, these are simply found *via* a relationship analogous to equation (6):

$$K(\Gamma) = 4.0393 \times 10^{-4} \nu(\Gamma)_{\text{CO}}^2 \quad (20)$$

The number of force constants required for the force fields of carbonyls depends, of course, on the number of CO groups and the point group of the complex. For example,  $\text{Mo}(\text{CO})_5\text{PF}_3$  is treated as a  $C_{4v}$  structure based on an octahedron. This is not strictly true since the  $\text{PF}_3$  ligand has a threefold rather than a fourfold axis of symmetry and  $\text{Mo}(\text{CO})_5\text{PF}_3$  is, at best,  $C_s$ . However, most ligands behave more or less as single spherical entities and it is more convenient to regard them as such. However, a note of caution must be registered in that some ligands, for example the phosphites, such as  $\text{P}(\text{OMe})_3$ , distort the CO framework significantly and reduce the symmetry away from the idealized situation.

Extending the example of  $\text{Mo}(\text{CO})_5\text{PF}_3$  further, this complex has four equivalent CO groups *cis* to the  $\text{PF}_3$

ligand and a chemically distinct CO group *trans* to the  $\text{PF}_3$ . Therefore the EFFF of this complex needs two CO-stretching force constants,  $k_1$  for the more numerous CO groups *cis* to  $\text{PF}_3$  and  $k_2$  for the CO group *trans* to  $\text{PF}_3$ . In the  $F$  matrix of the molecular force field these constants would occupy the positions along the diagonal. Furthermore, we need off-diagonal terms in the  $F$  matrix, that is, the interaction constants. There are three interaction constants:  $k_{11(\text{cis})}$  linking mutually *cis* equatorial CO groups,  $k_{11(\text{trans})}$  for mutually *trans* CO groups and  $k_{12}$  linking the axial CO group with the equatorial CO groups. The EFFF  $F$  matrix for this molecule is shown below:

$$F : \begin{vmatrix} k_1 & k_{11(\text{cis})} & k_{11(\text{trans})} & k_{11(\text{cis})} & k_{12} \\ k_{11(\text{cis})} & k_1 & k_{11(\text{cis})} & k_{11(\text{trans})} & k_{12} \\ k_{11(\text{trans})} & k_{11(\text{cis})} & k_1 & k_{11(\text{cis})} & k_{12} \\ k_{11(\text{cis})} & k_{11(\text{trans})} & k_{11(\text{cis})} & k_1 & k_{12} \\ k_{12} & k_{12} & k_{12} & k_{12} & k_2 \end{vmatrix} \quad (21)$$

The text below describes the force fields and possible  $\nu(\text{CO})$  absorptions of the various types of mononuclear transition metal carbonyl complex. Although it is not an exhaustive survey, most of the important groups are covered. A summary of the structures covered is given in Table 7. Where a ligand is denoted as L it is a two-electron donor (e.g.,  $\text{PF}_3$ ) and where it is X it is a one-electron donor (e.g., Br).

Before attempting to calculate a force field, it is best to ensure that the wavenumbers of the  $\nu(\text{CO})$  bands are accurately known and the relative intensities are also known. A very useful quantity to have at hand at the start of the process that changes frequencies into force constants is  $\sum K$ , the sum of all the symmetry force constants (allowing for degeneracy). For example,  $\sum K$  for  $\text{Cr}(\text{CO})_6$  would be found by:

$$\sum K = K(a_{1g}) + 2K(e_g) + 3K(t_{1u}) \quad (22)$$

For any carbonyl complex  $\text{M}(\text{CO})_x(\text{L})_y$ , the mean CO-stretching force constant ( $\bar{k}_{\text{CO}}$ ) is

$$\bar{k}_{\text{CO}} = \frac{\sum K}{x} \quad (23)$$

where  $x$  is the number of CO groups. In any iterative procedure for calculating force constants,  $\bar{k}_{\text{CO}}$  is a very good starting point.

### 5.2 Monocarbonyls

The case of a monocarbonyl is the most simple. The force constant is given simply by

$$k_1 = 4.0393 \times 10^{-4} \nu_{\text{CO}}^2 \quad (24)$$

There will be a weak feature to lower frequency due to  $^{13}\text{C}^{16}\text{O}$  in natural abundance. Check that this band is in

**Table 7** Energy factored force fields of mononuclear carbonyl complexes

| Point group    | Example                                                   | $\nu(\text{CO})$ modes  | Force constants |                                                    |
|----------------|-----------------------------------------------------------|-------------------------|-----------------|----------------------------------------------------|
|                |                                                           |                         | Stretching      | Interaction                                        |
| Monocarbonyls  |                                                           |                         |                 |                                                    |
| $C_{nv}$       | $\text{Mo}(\text{L})_5\text{CO}$                          | $a_1$                   | $k_1$           |                                                    |
| Dicarbonyls    |                                                           |                         |                 |                                                    |

the correct place by multiplying the  $\nu(^{12}\text{C}^{16}\text{O})$  frequency by 0.977709 to give that for  $\nu(^{13}\text{C}^{16}\text{O})$ .

### 5.3 Dicarbonyls

The force field for dicarbonyls with equivalent CO groups (e.g.,  $\text{Ni}(\text{CO})_2(\text{L})_2$  complexes<sup>24</sup>) is straightforward, since there are as many absorptions as there are force constants. The secular equations and force constants for a  $C_{nv}$  dicarbonyl are shown in Table 8, but for different point groups the only difference is the convention of labeling the symmetric and asymmetric modes:

In general, the lower frequency ( $b_2$ ) mode will be considerably stronger than the  $a_1$  mode. The C–M–C bond angle,  $\theta$ , can be estimated from the relative intensities of the  $a_1$  and  $b_2$  bands:

$$\theta = 2 \tan^{-1} \sqrt{\frac{I(b_2)}{I(a_1)}} \quad (25)$$

**Table 8**  $\text{M}(\text{CO})_2$  dicarbonyl with  $C_{nv}$  or higher symmetry

|             |                            |
|-------------|----------------------------|
| $K(\Gamma)$ | $K(a_1) = k_1 + k_{11}$    |
|             | $K(b_2) = k_1 - k_{11}$    |
|             | $\sum K = K(a_1) + K(b_2)$ |
| Force field | $k_1 = \sum K / 2$         |
|             | $k_{11} = k_1 - K(b_2)$    |

where  $I(b_2)$  and  $I(a_1)$  are the intensities of the absorptions.

An identical treatment to that above can be carried out for dicarbonyls of point group  $C_s$  (e.g.,  $\text{Co}(\text{CO})_2(\text{NO})(\text{L})$  complexes<sup>25</sup>). The only difference is that the  $a_1$  mode is now of symmetry  $a'$  and the  $b_2$  mode is reclassified as  $a''$ . In octahedral species of the type *trans*- $\text{M}(\text{CO})_2(\text{L})_4$  (point group  $D_{4h}$ ) and trigonal-bipyramidal structures of the type *trans*- $\text{M}(\text{CO})_2(\text{L})_3$  (point group  $D_{3h}$ ) there are two  $\nu(\text{CO})$  vibrations, a symmetric and an asymmetric stretch.<sup>26</sup> The symmetric stretch is at higher frequency (by virtue of the fact that CO–CO interaction constants are always positive) and is Raman-active only. If both frequencies are known, the procedure is identical to complexes of the  $C_{2v}$  type. If Raman spectra are not available, the force constants can be estimated by using equation (18) and the asymmetric stretch.

In dicarbonyls where the CO groups are chemically different the force field is underdetermined with three force constants ( $k_1$ ,  $k_2$ , and  $k_{12}$ ) and only two absorptions which have the same symmetry ( $a'$  for  $C_s$ ,  $a$  for  $C_1$ ). Without any further information, only equation (18) can be invoked, since

$$k_{12} = A - B \left\{ \frac{[K(a)_1 + K(a)_2]}{2} \right\} \quad (26)$$

This would, assuming a particular C–M–C bond angle to provide appropriate values of  $A$  and  $B$ , enable an approximate force field to be calculated. That said, accurate force constants can only be obtained from the isotopic spectrum.

## 5.4 Tricarbonyls

Tricarbonyls with  $D_{3h}$  symmetry (see Table 9) occur commonly in complexes of the type  $\text{Fe}(\text{CO})_3(\text{L})_2$ <sup>27</sup> (and their ruthenium and osmium analogs). There are two  $\nu(\text{CO})$  modes, an  $a'_1$  symmetric stretch, which is inactive in the IR, and an  $e'$  stretch. These two absorptions are sufficient to determine the two force constants.

The  $a'_1$  band is IR-inactive but is often present as a very weak feature. If Raman spectra are not available to confirm the location of this absorption, the force field can be determined from the isotopic spectrum. Naturally abundant  $^{13}\text{C}^{16}\text{O}$  would provide for 3.3% of the molecules being isotopically substituted and this would give rise to the usual satellite bands.

Examples of tricarbonyl molecules with  $C_{3v}$  symmetry are not difficult to find (see Table 10). A multitude of  $\text{Ni}(\text{CO})_3\text{L}$ <sup>24</sup> and *fac*- $\text{M}(\text{CO})_3(\text{L})_3$  (M = Cr, Mo, W)<sup>28</sup> complexes fall into this category. The treatment is very similar to that for the  $D_{3h}$  tricarbonyls above but, if anything, simpler since both absorptions ( $a_1 + e$ ) are active in both the IR and Raman.

The force field is, therefore, fully determined. Since both absorptions are present in the infrared, it is unlikely that isotopic data would be required for  $C_{3v}$  tricarbonyl complexes.

Tricarbonyl complexes of  $C_{2v}$  symmetry are represented by the octahedral *mer*- $\text{M}(\text{CO})_3(\text{L})_3$  species<sup>29</sup> and equatorially substituted trigonal-bipyramid  $\text{M}(\text{CO})_3(\text{L})_2$  complexes (see Table 11). There are three  $\nu(\text{CO})$  modes ( $2a_1 + b_2$ ) and four force constants ( $k_1, k_2, k_{11}, k_{12}$ ) in the force field. The higher frequency  $a_1$  mode tends to be sharp and of quite low relative intensity. The  $b_2$  mode is much stronger than the low-frequency  $a_1$  mode, but the two may overlap. The problem is, in any case, underdetermined with one degree of freedom. If  $k_1$  is defined as the force constant for the two equivalent CO groups and  $k_2$  as the force constant for

| Force field | $k_1 = \sum K / 3$<br>$k_{11} = k_1 - K(e)$                                    |

Table 11  $\text{M}(\text{CO})_3$  tricarbonyl with  $C_{2v}$  symmetry

|             |                                                                                                                                                                              |
|-------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $K(\Gamma)$ | $a_1: \begin{vmatrix} k_1 + k_{11} - K & \sqrt{2}k_{12} \\ \sqrt{2}k_{12} & k_2 - K \end{vmatrix} = 0$<br>$K(b_2) = k_1 - k_{11}$<br>$\sum K = K(a_1)_1 + K(a_1)_2 + K(b_2)$ |
| Force field | $k_1 = (K(b_2) + A)/(1 + B)$<br>$k_{11} = k_1 - K(b_2)$<br>$k_2 = \sum K - 2k_1$<br>$k_{12} = A - B[k_1 + k_2]/2$                                                            |

the single, chemically different CO group, two interaction constants ( $k_{11}$  and  $k_{12}$ ) are required to complete the force field. Although a full solution of the force field is always possible using isotopic CO, a simpler solution will be found *via* equation (18).

This method of calculating the force field introduces two constraints where only one is strictly necessary. An iterative balancing of the force constants may be more illuminating. A better solution would be found using isotopic data. Given reasonable spectra showing enough satellite bands, the force field can be manipulated to give a best fit.

An important class of tricarbonyls are of  $C_s$  symmetry (see Table 12). These include such species as *fac*- $\text{Re}(\text{CO})_3(\text{L}-\text{L})\text{X}$  where L-L is a bidentate ligand (for example, 2,2'-bipyridyl) and X is a halogen or pseudohalogen.<sup>30</sup> There has been considerable interest in these species recently as they have interesting catalytic<sup>31</sup> and photochemical<sup>32</sup> properties. The EFFF treatment for these complexes is very similar to that for the  $C_{2v}$  tricarbonyls.

The infrared spectrum of these complexes is like the *fac*-substituted  $\text{M}(\text{CO})_3(\text{L})_3$  complexes where the  $e$  mode is split. The higher frequency  $a'$  mode is often relatively quite intense and the lower  $a'$  and  $a''$  are usually quite close in frequency and, although the latter is usually more intense, overlap may make it difficult to assign them unambiguously from the IR spectrum alone. Judicious use of equation (18) usually solves assignment problems.

Table 12  $\text{M}(\text{CO})_3$  tricarbonyls with  $C_s$  symmetry akin to *fac*- $\text{Re}(\text{CO})_3(\text{L}-\text{L})\text{X}$  complexes

## 5.5 Tetracarbonyls

The force field of tetrahedral  $M(CO)_4$  (e.g.,  $Ni(CO)_4$ ,  $[Co(CO)_4]^-$ ) is fully determined if the  $a_1$  (Raman) and  $t_2$  (IR and Raman) are both observed (see Table 13).

If the Raman spectrum is not available, the force field can be determined from the naturally occurring isotopic species ( $\approx 4.4\%$  abundance), which belongs to the point group  $C_{3v}$ , or by using equation (18).

Most octahedral disubstituted  $M(CO)_4(L)_2$  complexes have a cis isomer of  $C_{2v}$  symmetry (discussed below) and a trans isomer, which has  $D_{4h}$  symmetry if the ligand has fourfold symmetry or is a single atom (see Table 14).  $D_{4h}$  tetracarbonyl molecules have a center of symmetry and none of the vibrations appear in both IR and Raman spectra. In the CO region there are three vibrations:  $a_{1g}$  (Raman),  $b_{2g}$  (Raman), and  $e_u$  (IR). Given all three  $\nu(CO)$  frequencies, the force field ( $k_1$ ,  $k_{11(cis)}$ , and  $k_{11(trans)}$ ) is fully determined.

The IR spectrum of complexes such as these will therefore show a single band (the  $e_u$  mode). If Raman data are unavailable, and the supposedly IR-inactive bands are not observed as weak features,<sup>33</sup> reasonably accurate force constants can be obtained from equation (18). More usually, asymmetry in the ligand or distortion of the force field due to solvent–CO interactions makes both the Raman-active bands very slightly allowed in the IR. Indeed, *trans*-[(*i*-PrO)<sub>3</sub>P]<sub>2</sub>Mo(CO)<sub>4</sub> shows pronounced effects due to the irregular packing of the phosphite ligands. Not only are the  $a_{1g}$  and  $b_{2g}$  bands readily observable, but the  $e_u$  band is rather broader than is usually found. In the absence of such data, isotopic spectra will provide enough information to resolve the problem. The monosubstituted molecule is present at 4.4% (natural abundance). The force fields of this type of molecule invariably support Cotton's approximation

**Table 13**  $M(CO)_4$  tetracarbonyls with  $T_d$  symmetry

|             |                                                                                    |

|             |                                                                                                                                                                            |
|-------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $K(\Gamma)$ | $a_1: \begin{vmatrix} k_1 + 2k_{11} - K & \sqrt{3}k_{12} \\ \sqrt{3}k_{12} & k_2 - K \end{vmatrix} = 0$<br>$K(e) = k_1 - k_{11}$<br>$\sum K = K(a_1)_1 + K(a_1)_2 + 2K(e)$ |
| Force field | $k_1 = (K(e) + A) / (1 + B)$<br>$k_{11} = k_1 - K(e)$<br>$k_2 = \sum K - 2k_1$<br>$k_{12} = A - B[k_1 + k_2] / 2$                                                          |

(equation 10) in that:

$$K(b_{2g}) \approx k_1 \quad (27)$$

If a species  $M(CO)_4$  is intermediate between tetrahedral and square planar, it belongs to the point group  $D_{2d}$ . The  $a_{1g}$ ,  $b_{2g}$ , and  $e_u$  modes of the  $D_{4h}$  structure are relabeled  $a_1$ ,  $b_2$ , and  $e$ , respectively. All three modes are Raman-active, although the intensity of the  $e$  mode in the Raman spectrum is likely to be low if the distortion from square planar is small. The  $a_1$  mode remains, formally, IR-inactive. The force field can be determined by using the equations for the  $D_{4h}$  tetracarbonyl above. It has been suggested that octahedral species of the  $D_{4h}$  type show some distortion toward  $D_{2d}$ , as the ' $b_{2g}$ ' mode of these complexes is often observed in their IR spectrum. This does not explain the appearance of the ' $a_{1g}$ ' mode in the IR and it is likely that some ligands (e.g.,  $P(OR)_3$ ) cause a considerable overall reduction in symmetry.

Many  $Fe(CO)_4L$ ,  $Ru(CO)_4L$ , and  $Os(CO)_4L$  complexes<sup>34</sup> have  $C_{3v}$  symmetry, along with a large number of  $Co(CO)_4L$  compounds (see Table 15).<sup>35</sup> On the basis of the trigonal-bipyramidal structure, these complexes have a single ligand, occupying an axial site. Typically their IR spectra show a weak, sharp absorption at high frequency (the  $a_1$  mode that is primarily due to the symmetric breathing mode of the equatorial CO groups), a moderately strong absorption (of  $a_1$  symmetry, due to the motion of the axial CO group), and a very strong absorption at lower frequency (the asymmetric  $e$  mode). Unfortunately, the force field is underdetermined and it is necessary to resort to equation (18) for approximate force constants or to utilize isotopic spectra for an exact solution. At natural abundance, 1.1% of the molecules will have a  $^{13}C^{16}O$  group in an axial position and 3.3% will be substituted in an equatorial position. The axially substituted molecule retains the symmetry of the parent. The equatorially substituted molecule belongs to the point group  $C_s$  and has four ( $3a' + a''$ )  $\nu(CO)$  modes. If all the parent and naturally occurring isotope bands were observed, there would be eight frequencies with which to fix four force constants. It is unlikely, however, that this would be the case as all but two of the isotope bands are likely to be very weak. The use of equation (18) to fix at least one of the interaction constants makes the calculation of an approximate force field for these molecules quite simple.

**Table 16**  $M(\text{CO})_4$  tetracarbonyls with  $C_{2v}$  symmetry

|             |                                                                                                   |

|             | $\sum K = K(a_1)_1 + K(a_1)_2 + K(b_1) + K(b_2)$                                                  |
| Force field | $k_1 = (K(b_1) + A)/(1 + B)$                                                                      |
|             | $k_{11} = k_1 - K(b_1)$                                                                           |
|             | $k_2 = (\sum K - 2k_1)/2$                                                                         |
|             | $k_{22} = k_2 - K(b_2)$                                                                           |
|             | $k_{12} = A - B[k_1 + k_2]/2$                                                                     |

Tetracarbonyls with  $C_{2v}$  symmetry (see Table 16), such as *cis*- $M(\text{CO})_4(\text{L})_2$  ( $M = \text{Cr}, \text{Mo}, \text{W}$ ) and  $M(\text{CO})_4\text{L}$  ( $M = \text{Fe}, \text{Ru}, \text{Os}$ ;  $\text{L}$  in an equatorial position in a trigonal bipyramid) are common.<sup>33,36,37</sup> There are four  $\nu(\text{CO})$  absorptions ( $2a_1 + b_1 + b_2$ ) and five force constants ( $k_1, k_2, k_{11}, k_{22}, k_{12}$ ), which means that the force field is underdetermined with one degree of freedom. One of the  $a_1$  modes is at higher frequency and of lower intensity than the other three modes and the lower frequency  $a_1$  mode is always higher in frequency than the  $b_2$  mode. The ordering of the low-frequency  $a_1$  and the  $b_1$  mode is not easily predicted. Indeed, the IR spectrum of  $\text{Mn}(\text{CO})_4\text{NO}$ , which is of this class, was initially confusing since the  $b_1$  and low-frequency  $a_1$  are accidentally degenerate.<sup>38</sup>

Using equation (18) to determine the force fields of octahedral *cis*- $M(\text{CO})_4(\text{L})_2$  complexes can be done in two ways. Either the  $b_1$  or the  $b_2$  modes can be used to obtain a set of force constants and the others can then be calculated. For equatorially substituted  $M(\text{CO})_4(\text{L})$  complexes based on a trigonal bipyramid, the only variation is in changing the values of  $A$  and  $B$  in equation (18). While the force fields that this method produces are not exact, they are usually good enough to predict the  $a_1$  modes with reasonable accuracy and enable the  $^{13}\text{C}^{16}\text{O}$  satellite bands to be assigned. At natural abundance, 2.2% of the molecules will be substituted in an axial position and 2.2% in an equatorial position. All together, there are six possible absorptions because of the naturally occurring  $^{13}\text{C}^{16}\text{O}$  in addition to the four modes of the all- $^{12}\text{C}^{16}\text{O}$  molecule.

Of even lower symmetry are the  $C_s$ , octahedral *cis*- $M(\text{CO})_4(\text{L}_1)(\text{L}_2)$  complexes. The power of the EFFF in fitting isotopic spectra is, perhaps, best illustrated with a complex of this type: Poliakoff's matrix-isolated fragment *cis*- $\text{Cr}(\text{CO})_4\text{CS}$ .<sup>39</sup> The spectrum of a  $C_s$  tetracarbonyl complex shows three reasonably strong bands (all  $a'$  symmetry) and a very strong band ( $a''$  symmetry), although overlap may reduce this number. The force field is badly underdetermined, with three degrees of freedom. Even so, using equation (18) gives surprisingly accurate results.

## 5.6 Pentacarbonyls

Pentacarbonyliron(0) is the best known example of a pentacarbonyl complex. Others in this category include  $[\text{Mn}(\text{CO})_5]^-$ ,  $[\text{Cr}(\text{CO})_5]^{2-}$ ,  $\text{Ru}(\text{CO})_5$ , and  $\text{Os}(\text{CO})_5$ . As they have  $D_{3h}$  symmetry (see Table 17), the energy factored force field requires five force constants but there are only four  $\nu(\text{CO})$  frequencies (only two of which appear in the infrared) so the force field is underdetermined. Two of the  $\nu(\text{CO})$  modes are fully symmetrical ( $a'_1$ ) and are IR-inactive. The asymmetric stretches are labeled  $a'_2$  (due to the stretching of the axial CO groups) and  $e'$  (due to stretching of the equatorial CO groups). The  $e'$  mode is IR and Raman-active; the  $a'_2$  mode is active in the IR only.

With the force field, we must use equation (18) or isotopic data to solve the force field. At natural abundance, isotopic labeling will occur in axial and equatorial positions, in 2.2% and 3.3% of the molecules, respectively. The axially substituted species belongs to the point group  $C_{3v}$ . The equatorially substituted species belongs to the point group  $C_{2v}$ . The  $a'_2$  and one of the  $e'$  modes of the parent are relabeled  $b_1$  and  $b_2$ , but are otherwise unchanged. The remaining modes belong to the representation  $a_1$ . Thus, there will be a total of six isotope bands in the IR spectrum of trigonal-bipyramidal  $M(^{12}\text{C}^{16}\text{O})_4(^{13}\text{C}^{16}\text{O})$ . Two will be readily apparent as satellites of the two IR absorptions, but the others will be much weaker. However, the observation of two isotope bands in the IR still leaves the problem underdetermined and isotopic enrichment by CO exchange is the only realistic answer to solving the force field and providing accurate force constants.

Complexes of the type  $M(\text{CO})_5\text{L}$  (e.g.,  $\text{Mo}(\text{CO})_5\text{PF}_3$ ,  $\text{Cr}(\text{CO})_5\text{CS}$ ,  $\text{HMn}(\text{CO})_5$ ,  $\text{BrMn}(\text{CO})_5$ ) are among the most common and widely studied of carbonyl compounds.<sup>40</sup> There are, given both IR and Raman spectra, four  $\nu(\text{CO})$  absorptions ( $2a_1 + b_2 + e$ ). At highest frequency is a generally sharp, often weak, feature that is (mainly) due to the in-phase (hence  $a_1$  symmetry) motion of the four equatorial CO groups (see Table 18). To lower frequency is the  $b_2$  mode which is, strictly, Raman-active only. However, this band very often appears as a weak feature in the IR spectrum, arising from asymmetric effects from either the ligand or the solvent.

|-------------|----------------------------------------------------------------------------------------------------------------|
| $K(\Gamma)$ | $a_1: \begin{vmatrix} k_1 + 2k_{11(cis)} + k_{11(trans)} - K & 2k_{12} \\ 2k_{12} & k_2 - K \end{vmatrix} = 0$ |
|             | $K(b_2) = k_1 - 2k_{11(cis)} + k_{11(trans)}$                                                                  |
|             | $K(e) = k_1 - k_{11(trans)}$                                                                                   |
|             | $\sum K = K(a_1)_1 + K(a_1)_2 + K(b_2) + 2K(e)$                                                                |
| Force field | $k_1 = (K(e) + A)/(1 + B)$                                                                                     |
|             | $k_{11(trans)} = k_1 - K(e)$                                                                                   |
|             | $k_2 = \sum K - 4k_1$                                                                                          |
|             | $k_{11(cis)} = (k_1 - K(b_2) + k_{11(trans)})/2$                                                               |
|             | $k_{12} = A - B[k_1 + k_2]/2$                                                                                  |

Ligand asymmetry cannot be the whole story, as  $Mn(CO)_5Br$  has a weak IR absorption corresponding to the  $b_2$  mode. The remaining bands, as seen in the IR spectrum, are a very strong  $e$  mode (weak in the Raman) and a fairly strong  $a_1$  mode that is mainly due to the stretching of the CO group trans to the ligand L. The order of the  $e$  and low-frequency  $a_1$  modes is largely determined by the ligand. For strong  $\pi$ -acceptors (e.g., CS,  $PF_3$ ), the  $a_1$  mode is at higher frequency than the  $e$  mode. The situation is reversed for weaker  $\pi$ -acceptors (e.g.,  $PPh_3$ ,  $PMe_3$ ). The number of force constants exceeds the  $\nu(CO)$  absorptions by one and, so, the EFFF is underdetermined.

For more accurate force constants, we must use isotopic data. At natural abundance, 1.1% of the molecules will have a  $^{13}C^{16}O$  group in an axial position and 4.4% will be isotopically substituted in an equatorial position. The axially substituted molecule retains the symmetry of the parent and only the  $a_1$  modes are affected by the isotopic CO group. The high frequency  $a_1$  mode of the axially substituted molecule is (for  $^{13}C^{16}O$  in natural abundance) almost certainly too weak to be detected. The lower frequency  $a_1$  mode will be very weak. The equatorially substituted molecule is of symmetry  $C_s$  and responsible for the stronger satellite bands. The  $a''$  mode of  $cis-M(^{12}C^{16}O)_4(^{13}C^{16}O)L$  is identical to the  $e$  mode of the parent and gives no new information. However, if one or more of the  $a'$  modes can be located they can be used to remove the degree(s) of freedom in the force field. The observation of the  $b_2$  mode in the IR spectrum has been taken to indicate ligand asymmetry reducing the nominal symmetry of  $M(CO)_5L$  complexes to  $C_s$  or lower. Additional to this, the  $e$  mode is usually broader than the other absorptions, which suggests a lifting of the twofold degeneracy.

## 5.7 Hexacarbonyls

Octahedral  $M(CO)_6^{1,6}$  is a straightforward case. There are three  $\nu(CO)$  absorptions ( $a_{1g}$  (Raman) +  $e_g$  (Raman) +  $t_{1u}$  (IR)) and three force constants in the force field ( $k_1$ ,  $k_{11(cis)}$ , and  $k_{11(trans)}$ ) (see Table 19).

The ordering  $K(a_{1g}) > K(e_g) > K(t_{1u})$  is unambiguous since the interaction constants are always positive.

**Table 19**  $M(CO)_6$  hexacarbonyls with  $O_h$  symmetry

|             |                                                     |
|-------------|-----------------------------------------------------|
| $K(\Gamma)$ | $K(a_{1g}) = k_1 + 4k_{11(cis)} + k_{11(trans)}$    |
|             | $K(e_g) = k_1 - 2k_{11(cis)} + k_{11(trans)}$       |
|             | $K(t_{1u}) = k_1 - k_{11(trans)}$                   |
|             | $\sum K = K(a_{1g})_1 + 2K(e_u) + 3K(t_{1u})$       |
| Force field | $k_1 = \sum K / 6$                                  |
|             | $k_{11(trans)} = k_1 - K(t_{1u})$                   |
|             | $k_{11(cis)} = (K(a_{1g}) - k_1 - k_{11(trans)})/4$ |

The monosubstituted species  $M(^{12}C^{16}O)_5(^{13}C^{16}O)$  occurs at natural abundance to the extent of nearly 7%. The species belongs to the point group  $C_{4v}$  and the  $b_2$  and  $e$  modes correlate with the  $e_g$  and  $t_{1u}$  modes, respectively, of  $M(^{12}C^{16}O)_6$ . The remaining modes are of symmetry  $a_1$ . Thus, the monosubstituted species should, in principle, give rise to three isotope bands. In the IR spectrum, one of these will be a lower frequency satellite of the strong  $t_{1u}$  mode, while the other two will be at a higher energy and much weaker.

## 6 APPLICATIONS OF CO FORCE CONSTANTS

There have been several attempts to use energy factored force constants, calculated from transition metal  $\nu(CO)$  spectra, as probes into the nature of metal–ligand bonding<sup>41</sup> or reactivity,<sup>42</sup> as indicators of bond order.<sup>43</sup> A comprehensive study of the success (or otherwise) of these various studies has been published.<sup>44</sup>

One of the most successful systems<sup>20</sup> uses ligand effect constants and the  $k_{CO}$  for the triatomic metal monocarbonyl  $M-C-O$ . Assuming that ligand effect constants are additive, this model uses the simple equation

$$k_{CO} = k_d + \sum e_L^{\theta} \quad (28)$$

The parameter  $k_d$  is the force constant for the isolated monocarbonyl  $M(CO)$ . The subscript ‘d’ draws attention to the fact that this parameter is more concerned with the number of d-electrons than the specific metal at the center. This means that  $Cr(CO)_6$ ,  $HMn(CO)_5$ , and  $[V(CO)_5PBU_3]^-$  will share a common value for  $k_d$  (viz.  $k_6 = 1387 \text{ N m}^{-1}$ ). The terms contained in the summation are the ligand effect constants, which are transferable between metal centers. The values of  $k_d$  used are given in Table 20. In Table 21 are ligand effect constants for a variety of ligands. For ligands in an octahedral setting, two ligand effects constants ( $e_L^{cis}$  and  $e_L^{trans}$ ) are required. In tetrahedra only one ( $e_L^{td}$ ) is needed and it is very easily calculated. For trigonal-bipyramidal species, three ( $e_L^{ax,ax}$ ,  $e_L^{ax,eq}$  and  $e_L^{eq,eq}$ ) are needed although  $e_L^{eq,eq}$  is not always necessary since a large number of ligands only occupy an axial position in these systems.

**Table 20**  $k_d$  Parameters

| Period          | $k_5$          | $k_6$ | $k_7$          | $k_8$ | $k_9$          | $k_{10}$ |
|-----------------|----------------|-------|----------------|-------|----------------|----------|
| 1 <sup>st</sup> | 1373           | 1387  | 1444           | 1498  | 1554           | 1610     |
| 2 <sup>nd</sup> | — <sup>a</sup> | 1389  | — <sup>a</sup> | 1506  | — <sup>a</sup> | 1636     |
| 3 <sup>rd</sup> | 1353           | 1381  | 1445           | 1498  | — <sup>a</sup> | 1613     |

<sup>a</sup>Not determined, but probably close to the other group members.

It is quite a simple task to calculate ligand effect constants from force constants and *vice versa*. For example, the force constants for a  $M(CO)_5L$  complex are given (in terms of equation 27) by:

$$\begin{aligned}
 k_1 &= k_d + 3e_{CO}^{cis} + e_{CO}^{trans} + e_L^{cis} \\
 k_2 &= k_d + 4e_{CO}^{cis} + e_L^{trans} \\
 k_{11(cis)} &= 180 - 0.0929k_1 \\
 k_{11(trans)} &= 241 - 0.1134k_1 \\
 k_{12} &= 180 - 0.0929(k_1 + k_2)/2
 \end{aligned} \quad (29)$$

Using these equations, we can calculate ligand effect constants for some new ligand or, alternatively, calculate

$\nu(CO)$  frequencies for a  $M(CO)_5L$  complex with a known ligand.

The method has enjoyed considerable success in predicting  $\nu(CO)$  frequencies for assumed structures<sup>45</sup> and assigning spectra. Much of the utility of the method stems from the ability to generate a force field for a supposed structure and then test this against experimental findings. For example, the  $\nu(CO)$  frequencies for the whole series of unsaturated  $Mo(CO)_{5-x}(PF_3)_x$  complexes isolated in  $CH_4$  matrices at 20 K were predicted with a mean accuracy of  $3\text{ cm}^{-1}$ .

The link between the matrix-isolation technique and metal carbonyl chemistry has had a relatively long and certainly fruitful history. The pairing began in the early 1960s with a series of experiments by Sheline and coworkers<sup>46</sup> using a variety of glassy matrices held at 77 K by liquid nitrogen. In 1969, Turner and Rest<sup>47</sup> began the study of carbonyls in less reactive matrices (e.g., argon) at lower temperatures (commonly 20 K). Comprehensive reviews of the matrix-isolation studies involving carbonyls exist.<sup>48</sup> Suffice it to say here that this work has produced some extremely interesting results and without using an energy factoring approach to the  $\nu(CO)$  modes it is difficult to see how the many structural determinations could have been carried out.

**Table 21** Ligand effect constants

| Ligand                                           | $e_L^{cis}$ | $e_L^{trans}$ | $e_L^{td}$ | $e_L^{ax,eq}$ | $e_L^{eq,eq}$ | $e_L^{ax,ax}$ |

Technological advances have allowed the development of time-resolved infrared (TRIR) techniques in recent years and they too have exploited the intense, sharp spectra of the transition metal carbonyls. Some TRIR work has now been carried out, which confirms earlier matrix work;<sup>49</sup> and a review was published<sup>50</sup> some time ago. TRIR involving metal carbonyl species is now a maturing technique, with a considerable number of publications logged over the past 10 years.

The understanding of metal carbonyl reactions at electrode surfaces is also being tackled via the IR spectra of the participating complexes,<sup>51</sup> as are the chemical changes occurring on zeolites.<sup>52</sup>

## 7 POLYNUCLEAR CARBONYL COMPLEXES

Although the IR spectra of mononuclear carbonyl complexes are well understood, difficulties arise when dealing with the spectra of dinuclear complexes (e.g.,  $\text{Mn}_2(\text{CO})_{10}$  and its substitution products), trinuclear species (e.g.,  $\text{Os}_3(\text{CO})_{12}$ ), and larger carbonyls. In principle, the methodology for calculating energy factored force constants from observed  $\nu(\text{CO})$  bands (using either all- $^{12}\text{CO}$  or isotopically enriched spectra) is identical with that employed so successfully for mononuclear complexes. The problems spring from the very large numbers of force constants required in the  $F$  matrix. Consider the  $\text{Mn}(\text{CO})_5$  fragment. This has (given IR and Raman spectra) four  $\nu(\text{CO})$  modes ( $2a_1 + b_2 + e$ ) and five force constants. The problem has one degree of freedom but, with a little data from isotopes, is relatively easily solved. Dimanganese decacarbonyl has seven  $\nu(\text{CO})$  modes:<sup>53</sup> two  $a_1$  modes (Raman only), two  $b_1$  modes (IR only), and three doubly degenerate  $e$  modes ( $e_1 + e_2 + e_3$ ) of which only the  $e_3$  mode is IR-active. In addition to the five force constants for the  $\text{Mn}(\text{CO})_5$  fragments, there are another four interaction constants linking CO groups on different metals. This makes available seven  $\nu(\text{CO})$  fundamentals with which to calculate nine force constants, that is, two degrees of freedom. These 'through-space' interaction constants are generally smaller than those linking CO groups on the same metal but are certainly significant. There are few studies dealing with the force fields of polynuclear carbonyl complexes.<sup>54</sup>

For larger numbers of metal atoms surrounded by CO groups, the situation becomes quite perplexing. Instead of gradually increasing in complexity as the number of metal atoms increases, the IR spectra become extremely sparse with very few  $\nu(\text{CO})$  bands. One interpretation is that there is an ' $F$  matrix collapse', with all the small through-space interactions tending to zero and the  $F$  matrix becoming quasi-diagonal. Supporting this view is the observation that partial  $^{13}\text{CO}$  enrichment creates very few new absorptions and not the forest that might be expected.

There is much work still to be done on the force fields of polynuclear species and, with that area of carbonyl chemistry

forming a sizable percentage of all carbonyl research, the work is overdue.

## 8 INTENSITIES

Apart from a fleeting mention earlier, the numerical analysis of the relative intensities of  $\nu(\text{CO})$  bands has not been elaborated on in this article. The topic of  $\nu(\text{CO})$  intensities has been authoritatively reviewed by Burdett.<sup>55</sup> In general, the use of intensity data depends on the nature of the carbonyl complex. If all the CO groups are chemically equivalent and the force field is fully determined (e.g., *cis*- $\text{Cr}(\text{CO})_2(\text{PMe}_3)_4$ ,  $\text{Ni}(\text{CO})_3\text{PMe}_3$ ), there are few problems and the geometry of the molecule can be calculated from the relative intensities of the  $\nu(\text{CO})$  bands. Indeed, for all such cases the geometry of the  $\text{M}(\text{CO})_n$  unit can be determined without reference to the force constants. The situation becomes far more complex when there are chemically inequivalent CO groups (e.g.,  $\text{HMn}(\text{CO})_5$ ,  $\text{Fe}(\text{CO})_4\text{PMe}_3$ ). Regardless of the symmetry, there will be as many symmetric stretches as there are different types of CO group. Since these modes will mix through the off-diagonal terms in the  $F$  matrix, the intensities associated with these vibrations will be redistributed. This generates two problems. Firstly, to ascertain the degree of mixing, the force field must be accurately known. Secondly, the dipole change caused by the vibration of one group may well be different to that caused by a chemically different group in the same molecule. In the case of  $C_{4v}$  pentacarbonyl complexes, the problem has been thoroughly investigated and, on the whole, bond angles calculated from intensities are in good agreement, where they can be checked, with observed bond angles (from X-ray data). This general confidence in the method tends to suggest that the calculation of bond angles from intensity considerations for matrix-isolated species is likely to be valid.

However, there is a caveat to add at this point. The fluctuating dipoles responsible for the infrared intensities may not, in fact, lie along the lines described by the atoms. So, while we can calculate 'geometries' we may not, in truth, be describing angles between bonds but angles between dipoles. The contribution of other ligands into this complex problem has yet to be quantified and our present level of understanding only allows us to offer general conclusions about bond angles. The curious  $\nu(\text{CO})$  intensities of  $\text{Cr}(\text{CO})_5\text{CS}$ , where all the C-M-C bond angles are virtually  $90^\circ$  is a case in point. From the intensity data, we would conclude that the angle between the axial CO group and the equatorial groups was  $82^\circ$ .

## 9 RECENT DEVELOPMENTS

Studies involving the close scrutiny of the CO-stretching region of the spectrum have continued to be published. Indeed,

studies using TRIR (noted earlier) and the newer technique of carbonyl chemistry in supercritical fluids are highly dependent on the  $\nu(\text{CO})$  region. Fewer publications have followed the first studies of metal carbonyl photochemistry in supercritical fluids (such as  $\text{scXe}$  and  $\text{scCO}_2$ ) but the work that has been done (e.g., by Poliakoff<sup>56</sup> and coworkers) makes considerable use of the  $\nu(\text{CO})$  bands around  $2000\text{ cm}^{-1}$ .

Carbonyl spectra continue to be used to analyze  $\sigma/\pi$  bonding effects<sup>57</sup> and to monitor the processes taking place where CO groups are involved. Throughout the 1990s and into the new century, the number of studies dealing with  $\text{Re}(\text{CO})_3(\text{N-N})\text{X}$  complexes assumed plague proportions and each carried with it a more or less detailed description of the  $\nu(\text{CO})$  bands.

The combination of matrix-isolation and infrared spectroscopy has, since 1969, been used to identify carbonyl fragments (e.g.,  $\text{Cr}(\text{CO})_5$ ), radicals (e.g.,  $\text{Mn}(\text{CO})_5$ ) or unstable species (e.g.,  $\text{Pd}(\text{CO})_4$ ). This type of work continues<sup>58</sup> and the understanding of what is actually going on in the  $\nu(\text{CO})$  region is crucial to the success or otherwise of the study. Recent work in this field includes the reactions of zirconium and hafnium atoms with CO, manganese carbonyl nitrosyl complexes in solid argon, reactions of iron atoms with nitric oxide and carbon monoxide in excess argon and reactions of laser-ablated ruthenium atoms with CO and  $\text{H}_2$  mixtures. It would not be overstating the value of the  $\nu(\text{CO})$  spectra to say that, without this information the characterization of these matrix-isolated molecules would be impossible. The same is certainly true of species observed in TRIR studies where, in addition to structural information, we can also determine kinetic behavior.

There is no doubt that there remains much to be done and seen between  $2100$  to  $1850\text{ cm}^{-1}$ .

## Abbreviations

abt = 1-iminobenzene-2-thiolate (2-); acac = pentane-2,5-dionate (2-); bdt = benzene-1,2-dithiolate (2-); cat = catecholate (2-); benzene-1,2-diolate (2-); cyclam = 1,4,8,11-tetraazacyclotetradecane; depe = bis(diethylphosphino)ethane; dme = 1,2-dimethoxyethane; dppe = bis(diphenylphosphino)ethane; diphos = chelating bis(dialkyl)- or (diaryl)- phosphine; dme = 1,2-dimethoxyethane; en = 1,2-diaminoethane; mnt = maleonitriledithiolate (2-); *cis*-1,2-dicyanoethene-1,2-dithiolate (2-); OTf = trifluoromethanesulfonate (1-) (triflate (1-)); pz = pyrazine; py = pyridine; tdt = toluene-3,4-dithiolate (2-); tht = tetrahydrothiophene; tos = tosyl.

## 1 INTRODUCTION

Unlike its congener element molybdenum, tungsten does not play a significant industrial catalytic role. The element is encountered in a number of enzymes,<sup>1,2</sup> and following from earlier developments in the understanding and modeling of nitrogen fixation, the coordination chemistry of tungsten with simple nitrogen-based ligands was extensively developed.

During the last decade of the twentieth century, the inorganic and coordination chemistry of tungsten has

expanded. Among the major developments in this period have been (1) the introduction of a versatile range of polydentate ligands, including the tripodal tris(amido, triamidoamine, and tris(pyrazolyl)borato species, which have enabled the stabilization of novel species and chemistry; (2) continuing development of the chemistry of a range of complexes containing oxo and imido ligands; (3) increased activity and substantial sophistication in the chemical modeling of tungsto-enzymes structure, function and spectroscopy (see *Tungsten Proteins*) and (4) the development and rationalization of major areas of cluster chemistry (see *Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements*), including the assembly of polyoxoanions (see *Polyoxometalates*) and rational construction of chalcogenide-containing clusters.

Tungsten coordination has recently been comprehensively reviewed in *Comprehensive Coordination Chemistry*, particularly in the areas of mononuclear complexes,<sup>3</sup> dinuclear species containing single and multiple W–W bonds,<sup>4</sup> polyoxometallate synthesis, structure, and reactivity,<sup>5,6</sup> and chalcogen-containing cluster complexes.<sup>7</sup>

## 2 HALIDE AND CYANIDE COMPLEXES

Addition of one equivalent of anhydrous Et<sub>4</sub>NF in thf to [W(CO)<sub>5</sub>(thf)] afforded [Et<sub>4</sub>N]<sub>3</sub>[W<sub>2</sub>(CO)<sub>6</sub>(μ-F)<sub>3</sub>]. Reaction of this species, whose structure was confirmed crystallographically, with CO afforded the unstable [W(CO)<sub>5</sub>F]<sup>–</sup>, which containing labile CO ligands. In the absence of CO, this anion reverted to the dinuclear species or to [W(CO)<sub>6</sub>] on prolonged exposure to CO. Reaction of [W(CO)<sub>6</sub>] with LiI·OEt<sub>2</sub> afforded [W(CO)<sub>5</sub>I]<sup>–</sup>.

Reaction of [W(CO)<sub>6</sub>] with SbF<sub>5</sub> in the superacid mixture HF/SbF<sub>5</sub> afforded [W<sup>II</sup>(CO)<sub>6</sub>(FSbF<sub>5</sub>)] [Sb<sub>2</sub>F<sub>11</sub>], without loss of CO.

The tungsten(III) fluoride, K<sub>3</sub>[WF<sub>6</sub>] was obtained, as a mixture with K<sub>2</sub>[WF<sub>7</sub>], when K<sub>3</sub>[WF<sub>8</sub>] was reduced by tungsten metal. Treatment of WCl<sub>4</sub> with one equivalent of a reducing agent, usually Na/Hg or NaBHET<sub>3</sub> in toluene in the presence of PMe<sub>2</sub>Ph, afforded [(PMe<sub>2</sub>Ph)<sub>2</sub>Cl<sub>2</sub>W(μ-Cl)<sub>2</sub>WCl<sub>2</sub>(PMe<sub>2</sub>Ph)<sub>2</sub>]. By slight alteration of the stoichiometry, [(PMe<sub>2</sub>Ph)<sub>2</sub>ClW(μ-Cl)<sub>3</sub>WCl<sub>2</sub>(PMe<sub>2</sub>Ph)] was obtained, and the analogous bromide was prepared from WBr<sub>5</sub>. Monomeric [WCl<sub>3</sub>(PMe<sub>2</sub>Ph)<sub>3</sub>] was synthesized in the comproportionation reaction between [WCl<sub>4</sub>(PMe<sub>2</sub>Ph)<sub>2</sub>] and *trans*-[WCl<sub>2</sub>(PMe<sub>2</sub>Ph)<sub>4</sub>]. The stable mer-isomer was obtained as the major product, but low yields of the fac-isomer were isolated.

The dinuclear mixed-valence W<sup>II</sup>/W<sup>III</sup> species [(Me<sub>2</sub>S)Cl<sub>2</sub>W(μ-Cl)(μ-SPh)<sub>2</sub>WCl<sub>2</sub>(SMe<sub>2</sub>)] was obtained in the reaction between [WCl<sub>4</sub>(SMe<sub>2</sub>)<sub>2</sub>] with exactly one equivalent of Me<sub>3</sub>SiSPh. Treatment of this air-sensitive species with [Ph<sub>4</sub>As]Cl afforded [Cl<sub>3</sub>W(μ-Cl)(μ-SPh)<sub>2</sub>WCl<sub>2</sub>]<sup>2–</sup>, and analogous species [Cl<sub>3</sub>W(μ-Cl)(μ-SePh)<sub>2</sub>WCl<sub>3</sub>]<sup>2–</sup> and

the  $W^{IV}/W^{IV}$  species  $[Cl_3W(\mu-Se)(\mu-SePh)_2WCl_3]^{2-}$  were also isolated.

The seven-coordinate  $W^V$  fluoride  $K_2WF_7$  was prepared by reaction of  $KWF_6$  with LiF at high temperatures and under vacuum.

### 3 CYANIDE AND OTHER GROUP IV DONOR ATOM COMPLEXES

Reaction of  $[W(CO)_5(CN)]^-$  with  $[Cu(NCMe)_4]^+$  and  $PPh_3$  afforded  $[(OC)_5W(CN)Cu(PPh_3)_3]$  and the analogous isocyanide-bridged species  $[(OC)_5W(NC)Cu(PPh_3)_3]$  was obtained by addition of  $[Cu(PPh_3)_3CN]$  to  $[W(CO)_5(thf)]$  at low temperature. The latter slowly rearranged to the former.

Treatment of  $[W_2(CO)_{10}]^{2-}$  with  $Pb(NO_3)_2$  afforded  $[W(CO)_5]_4Pb_2^{2-}$  (1), where the Pb–Pb distance was short (2.82 Å).

Polymeric  $[W^{IV}(CN)_8(SnMe_3)_4]_n$  was obtained by reaction of  $K_4[W(CN)_8]$  with four equivalents of  $Me_3SnCl$ , whereas the hexanuclear  $[Mn(bipy)_2]_2(\mu-NC)_2[W^{IV}(CN)_4]_2(\mu-CN)_2$  was obtained by reaction of  $[Mn(bipy)_2Cl_2] \cdot 2H_2O \cdot EtOH$  with  $[W(CN)_8]^{4-}$  in aqueous media.

The  $W^V$  octacyanide  $[W(CN)_8]^{3-}$  formed adducts or clusters with other metals, an example being  $[Pt(en)_2]_3[W(CN)_8]_2$ , in which there was electronic coupling between the metal centers in solution and in the solid state. Magnetically interesting materials were obtained in reactions between  $[W(CN)_8]^{3-}$  and  $Mn^{2+}$ , namely  $[Mn^{II}_6(H_2O)_9\{W^V(CN)_8\}_4 \cdot 13H_2O]_n$  and  $[Mn_9(W(CN)_8)_6 \cdot 24EtOH] \cdot 2EtOH$ , the latter being high spin ( $S = 39/2$ ).

## 4 COMPLEXES WITH O-DONOR ATOMS

### 4.1 Tungstates and Oxo–tungsten Complexes

$[W^{IV}O(dppe)_2F]^+$  was prepared by reaction of *trans*- $[W(PPh_3)_2Cl_4]$  with  $BF_4^-$  and reacted with  $[Et_4N]OH$  giving *trans*- $[WO_2(dppe)_2]$ . On treatment of *trans*- $[WO_2(dppe)_2]$  with halide ions,  $NCS^-$  and  $MeI$ , the complexes

*trans*- $[W^{IV}O(dppe)_2X]$  ( $X = \text{halide, NCS, OMe}$ ) were formed.

Tungstate ion  $[WO_4]^{2-}$  reacted readily with the Lewis acid  $B(C_6F_5)_3$ , giving tetrahedral  $[WO\{OB(C_6F_5)_3\}_3]^-$ .

Treatment of  $WOCl_4$  with hexamethyldisiloxane in oxygenated solvents effected extraction of the chloride ion giving solvated species such as  $[WO_2Cl_2(MeOCH_2CH_2OMe)]$ , via elimination of  $Me_3SiCl$ . Polymeric  $[WO_2Cl_2]_n$  reacted with 1,3-dimethylalloxazine ( $L^1$ ) and bis(1-methylimidazol-2-yl)ketone ( $L_2$ ) afforded the monomeric six-coordinated species  $[WO_2Cl_2L^1]$  (2), and  $[WO_2Cl_2L^2]$  (3).

### 4.2 Alkoxide, Aryloxy, and Catecholate Complexes

#### 4.2.1 Alkoxide Complexes

Reaction of  $[W_2(NMe_2)_6]$  with an excess of cyclopentanol in hexane afforded first the dimethylamine adduct  $[W^{III}_2(O-c-C_5H_9)_6(NHMe_2)_2]$  but over a prolonged period in contact with cyclopentanol and  $NHMe_2$ , the green diamagnetic mixed-valence  $W^{III}W^V$  species  $[W_2(\mu-H)(\mu-O-c-C_5H_9)_2(O-c-C_5H_9)_5(NHMe_2)]$  (4) ( $R = c-C_5H_9$ ) was formed. The W–W distance (2.44 Å) is consistent with a double bond.

Reaction of  $[W_2(OCH_2Bu^t)_6(NHMe_2)_2]$  with  $P_4$  in hydrocarbon solvents afforded the phosphido-capped  $W_3^{IV}$

alkoxide  $[W_3(\mu^3-P)(\mu-OCH_2Bu^t)_3(OCH_2Bu^t)_3]$  (5), together with the previously known  $[W(\eta^3-P_3)(OCH_2Bu^t)(NHMe_2)]$ .

Treatment of  $[W(PMe_2Ph)_2Cl_4]$  with two equivalents of  $TiOCH_2CF_3$  afforded  $[W^{IV}Cl_2(OCH_2CF_3)_2(PMe_2Ph)_2]$ . Reaction of  $[WO_{2-n}S_n]^{2-}$  with  $SiClPh_3$  and  $Me_4phen$  (3,4,7,8-tetramethyl-1,10-phenanthroline) gave  $[WO_{2-n}S_n(OSiPh_3)_2(Me_4phen)]$  (6).

Reaction of  $[W_2(OCH_2Bu^t)_8]$  with pyridine-*N*-oxide, elemental sulfur, selenium, and  $Bu^t_3P^tE$  afforded  $[W^V_2(\mu-E)(\mu-OCH_2Bu^t)_2(OCH_2Bu^t)_6]$  (E = O, S, Se, or Te).

Anodic oxidation of metallic tungsten in methanol afforded a mixture of  $[W(OMe)_6]$  and  $[WO(OMe)_4]$ , and reaction of  $[W(NMe_2)_6]$  with pinacol afforded the tris-pinacolate (2-)  $[W(OCMe_2CMe_2O)_3]$ . Treatment of  $WCl_6$  with one or two equivalents of the silsesquinoxane  $R_7Si_7O_9(OH)_3$  afforded the bis(silsesquinoxanato) complexes (7).

#### 4.2.2 Aryloxide Complexes

Reaction of  $[WCl_4(SET_2)_2]$  with  $(OC_6H_3R_2)^-$  (R = Me,  $Pr^i$ ) afforded the nearly square-planar species  $[W^{IV}(OC_6H_3R_2)_4]$ . Reaction of substituted pyridines (L), dipyrityls, and phenanthrolines ( $L_2$ ) with *trans*- $[W(OC_6H_3Ph-C_6H_4-O,C)(PMePh_2)_2]$ , itself generated by sodium amalgam reduction of  $[W(OC_6H_3-2,6-Ph_2)_2Cl_4]$  in the presence of  $PMePh_2$ , gave  $[W(OC_6H_3Ph-C_6H_4-O,C)L_2]$  (7), in which the diphenylphenoxide ligands are cyclometallated, the complex having mutually trans O atoms and cis pyridine ligands. The complexes (8) exhibited sharp contact-shifted  $^1H$  NMR spectra, the amount of contact shifting being strongly dependent on the nature of the N-donor ligand L. Assignment of the signals in the  $^1H$  NMR spectra, as well as their temperature

dependence, indicated that there was a thermal equilibrium between a single ground state for the  $d^2$   $W^{IV}$  center and a triplet excited state, which underwent through-bond coupling to the ligand protons. The relative singlet-triplet energy gap for several ligand systems was calculated from the spectral data.

Reduction of  $[WCl_2(OAr)_4]$  (Ar =  $C_6H_3Cl_2-2,6$ ) by sodium amalgam afforded  $[W^VCl(OAr)_4(OEt_2)]$ , in which the ether is trans to Cl. Reaction of  $[WCl_4(OAr)_2]$  (Ar =  $C_6H_3Ph_2-2,6$ ) with an excess of  $LiBH_4$  or an equivalent of sodium amalgam in the presence of  $PMe_2Ph$  afforded  $[WCl_3(OAr)_2(PMe_2Ph)]$ , and  $WCl_2(OAr)_2(thf)$  was isolated following reduction by  $Mg(C_4H_6)_2$  in thf.

Reaction of  $WOCl_4$  with phenols ( $ArOH$ ) afforded  $[W^{VI}OCl_2(OAr)_2]$ . With aromatic diols, species such as  $[WO(OArOCl_2(thf)_2)]$  or  $[WOCl_3(OArOH) \cdot OEt_2]$  were formed, depending on solvents used. Reaction of  $WOCl_4$  with 1,3-dialkyl-*p*- $Bu^t$ calix[4]arene ( $R_2calH_2$ ; R = Me, Et) afforded  $[WOCl_2(R_2cal)]$  (9), whereas use of the unalkylated calixarene (R = H) gave  $[WO(cal)] \cdot n(\text{solvent})$  and  $[WO(cal)L]$  (L =  $H_2O$ ,  $MeCO_2H$ ). Reaction of  $[W(OCH_2CH_2O)_2(OAr)_2]$  with HCl afforded *trans*- $[WCl_2(OCH_2CH_2O)(OAr)_2]$  (Ar =  $C_6H_2Me_2-2,6$ ,  $C_6H_2Pr^i-2,6$  and  $C_6H_2Me_2-2,6$ ). The first structurally characterized complex containing  $W^{VI}-I$  bonds,  $[WI_2(OBu^t)_4]$ , was also reported.

#### 4.2.3 Catecholate Complexes

Treatment of  $[\text{W}(\text{CO})_5(\text{thf})]$  with two equivalents of  $[\text{Et}_4\text{N}][\text{OC}_6\text{H}_4\text{OH}]$  afforded the orange catecholato ( $2^-$ ) species  $[\text{Et}_4\text{N}]_2[\text{W}(\text{CO})_4(\text{O}_2\text{C}_6\text{H}_4)] \cdot \text{HOC}_6\text{H}_4\text{OH}$ , in which the catechol hydrogen-bonded to adjacent O atoms of the catecholato ( $2^-$ ) ligands, thereby forming a chain-like structure in the solid state. Treatment of this species with an excess of NaOMe afforded  $[\text{Et}_4\text{N}]_2[\text{W}(\text{CO})_4(\text{O}_2\text{C}_6\text{H}_4)]$ , and similar complexes containing  $[\text{O}_2\text{C}_6\text{H}_2\text{Bu}^t_2]^{2-}$  (di-*t*-butylcatecholate) were also isolated. The tetracarbonyl species reversibly decarbonylated, affording  $[\text{W}(\text{CO})_3(\text{O}_2\text{C}_6\text{H}_2\text{R}_2)]_2$  ( $\text{R} = \text{H}$  or But), and crystallographic studies showed the geometry of these five-coordinate species as intermediate between trigonal bipyramidal and square planar. A related amido-phenolato species  $[\text{W}(\text{CO})_3\{\text{O}(\text{NH})\text{C}_6\text{H}_4\}]^{2-}$  was also reported.

#### 4.2.4 Peroxide Complexes

Reaction of  $\text{WO}_3 \cdot \text{H}_2\text{O}$  with hydrogen peroxide (30%) followed by addition of  $\text{SiPh}_2(\text{OH})_2$  or  $[\{\text{Ph}_2\text{Si}(\text{OH})\}_2\text{O}]$  afforded dimeric species  $[\text{Ph}_2\text{SiO}_2\{\text{W}_2\text{O}_2(\mu\text{-O}_2)_2(\text{O}_2)_2\}]_2$ —(10), and  $[\{\text{Ph}_2\text{SiOW}(\text{O})(\text{O}_2)_2\}_2\mu\text{-O}]_2$ —(11).

#### 4.2.5 Carboxylato, Carbonato, and Related Complexes

Glycinato derivatives  $[\text{W}(\text{CO})_4\{\kappa^2\text{-O}_2\text{CCH}_2\text{NRR}'\text{-N},\text{O}\}]^-$  ( $\text{RR}' = \text{H}_2, \text{HMe}, \text{Me}_2$ ) were prepared by reaction of  $[\text{W}(\text{CO})_5(\text{thf})]$  with the corresponding glycine derivatives. Reaction of  $[\text{W}(\text{CO})_5(\text{NCMe})]$  with one equivalent of oxalate ion afforded  $[\text{W}(\text{CO})_4(\kappa^2\text{-O}_2\text{C}_2\text{O}_2)]^{2-}$ . With two equivalents of oxalate,  $[\text{W}_2(\text{CO})_{10}(\mu\text{-}\kappa^1\text{-O}_2\text{C}_2\text{O}_2)]^-$  was formed initially, and following loss of CO,  $[\text{W}_2(\text{CO})_8(\mu\text{-}\kappa^2\text{-O}_2\text{C}_2\text{O}_2)]^{2-}$  was generated.

Reaction of bicarbonate ion with  $[\text{W}(\text{CO})_5(\text{acetone})]$  or of  $[\text{W}(\text{CO})_5(\text{OH})]^-$  with  $\text{CO}_2$  afforded  $[\text{W}(\text{CO})_5\{\kappa^1\text{-OCO}(\text{OH})\}]^-$ . Insertion of COS into the W–O bond in  $[\text{W}(\text{CO})_5(\text{OC}_6\text{H}_3\text{Ph}_2\text{-2,6})]^-$  afforded  $[\text{W}(\text{CO})_5\{\text{SC}(\text{O})\text{OC}_6\text{H}_3\text{Ph}_2\}]^-$  (12).

Reaction of *trans*- $[\text{W}(\text{CO})(\text{N}_2)(\text{dppe})_2]$  with an excess of methanol of secondary amine under  $\text{CO}_2$  afforded  $[\text{W}^{\text{II}}\text{H}(\kappa^1\text{-OCO}_2\text{Me})(\text{CO})(\text{dppe})_2]$  or the carbamate species  $[\text{W}^{\text{II}}\text{H}(\kappa^2\text{-O}_2\text{CNR}_2(\text{CO})(\kappa^1\text{-dppe})(\kappa^2\text{-dppe}))]$ . Treatment of the latter with  $\text{AlEt}_3$  in thf under  $\text{CO}_2$  afforded *trans*- $[\text{W}(\text{CO})(\kappa^2\text{-OCO-C},\text{O})(\text{dppe})_2]$ .

Reaction of  $\text{WCl}_6$  or  $\text{WOCl}_4$  with salicylic acid ( $\text{H}_2\text{sal}$ ) followed by crystallization of the product from thf afforded  $[\text{W}^{\text{VI}}\text{OCl}(\text{Hsal}\text{-thf})(\text{sal})]$ . However, treatment of  $\text{WOCl}_4$  with three equivalents of salicylic acid gave  $[\{\text{WO}(\text{Hsal})(\text{sal})\}_2\text{O}]$ .

#### 4.2.6 Schiff Base Complexes

The dinuclear species  $[\text{W}_2(\text{CO})_8(\text{salen})]^{2-}$  was obtained by reaction of two equivalents of  $[\text{W}(\text{CO})_5(\text{thf})]$  with  $(\text{salen})^{2-}$ .

Reaction of  $[\text{W}(\text{CN})_3\text{O}_2]^{4-}$  with salicylaldehyde and 1,2-diaminoethane (precursors of the Schiff base salenH<sub>2</sub>) afforded  $[\text{W}^{\text{IV}}\text{O}(\text{CN})(\text{salen})]^{2-}$ .

## 5 COMPLEXES WITH SULFUR, SELENIUM, AND TELLURIUM DONOR ATOMS

### 5.1 Dithiolene Complexes

Reaction of  $[\text{W}(\text{CO})_5(\text{thf})]$  with  $[\text{HXYC}_6\text{H}_4]^-$  ( $\text{X} = \text{Y} = \text{S}$ ,  $\text{X} = \text{O}$ ,  $\text{Y} = \text{S}$ ,  $\text{X} = \text{NH}$ ,  $\text{Y} = \text{S}$ ) initially afforded  $[\text{W}(\text{CO})_4(\text{HXYC}_6\text{H}_4)]^-$ , but further treatment with  $\text{OMe}^-$  gave the dithiolate species  $[\text{W}(\text{CO})_4(\text{XYC}_6\text{H}_4)]^{2-}$ . These tetracarbonyl complexes gradually converted to tricarbonyl species on bubbling argon into acetonitrile solutions at 40 °C. Trigonal bipyramidal structures were determined for  $[\text{PPN}][\text{W}(\text{CO})_3\{\text{S}(\text{NH})\text{C}_6\text{H}_4\}]$  and  $[\text{PPN}][\text{W}(\text{CO})_3\{\text{SOC}_6\text{H}_4\}]$ , but  $[\text{PPN}]_2[\text{W}(\text{CO})_4(\text{S}_2\text{C}_6\text{H}_4)]$  was octahedral.

Reaction of  $[\text{W}(\text{CO})_3\text{L}_2\text{I}_2]$  ( $\text{L} = \text{PET}_3$ ,  $\text{PPh}_3$ ,  $\text{L}_2 = \text{dppe}$ ) with  $\text{mnt}^{2-}$  or  $\text{bdt}^{2-}$  afforded  $[\text{W}^{\text{II}}(\text{CO})_2\text{L}_2(\text{mnt})]$  and  $[\text{W}^{\text{II}}(\text{CO})_2\text{L}_2(\text{bdt})]$ . The related complexes  $[\text{W}^{\text{II}}(\text{CO})_2\text{L}_2(\text{S}_2\text{C}_2\text{S})]$  ( $\text{S}_2\text{C}_2\text{S}_2\text{CS} = (13)$ ) were prepared similarly.

Reduction of  $[\text{W}(\text{S}_2\text{C}_2\text{Me}_2)_3]$  by  $\text{Et}_4\text{NBH}_4$  afforded  $[\text{W}(\text{S}_2\text{C}_2\text{Me}_2)_3]^{2-}$  while  $[\text{WSe}_9]^{2-}$  or  $[\text{WSe}(\text{Se}_4)_2]^{2-}$  reacted with dimethylacetylenedicarboxylate, giving the tris(diselenolene) complex  $[\text{W}(\text{Se}_2\text{C}_2\text{R}_2)_3]^{2-}$  ( $\text{R} = \text{CO}_2\text{Me}$ ). Reaction of tetrathiapentalenedione,  $\text{C}_2\text{S}_4(\text{CO})_2$ , with  $[\text{WS}_4]^-$  afforded  $[\text{W}(\text{S}_2\text{C}_2\text{S}_2\text{CO}_3)]^{2-}$ . These ‘noninnocent’ species formally contain  $\text{W}(\text{IV})$ .

Treatment of  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{R}_2)_2]$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ) with  $\text{OH}^-$ ,  $\text{S}^{2-}$ , or  $\text{Se}^{2-}$  afforded  $[\text{W}^{\text{IV}}\text{E}(\text{S}_2\text{C}_2\text{R}_2)_2]^{2-}$  ( $\text{E} = \text{O}$ ,  $\text{S}$ ,  $\text{Se}$ ).

Bis(dithiolene) tungsten(IV) complexes have been synthesized for comparison with the active sites in tungsto-enzymes.  $[\text{WO}(\text{bdt})_2]^{2-}$  was prepared by borohydride reduction of  $[\text{WO}(\text{bdt})_2]^-$ , and the analogous  $[\text{WO}(\text{mnt})_2]^{2-}$  was prepared by reduction of  $[\text{W}^{\text{VI}}\text{O}(\kappa^2\text{-S}_2)(\text{mnt})_2]^{2-}$ . Reaction of  $[\text{WO}_2(\text{CN})_4]^{4-}$  with  $[\text{SC}(\text{H})=\text{C}(\text{Ar})\text{S}]^{2-}$  ( $\text{Ar} = \text{Ph}$ , 2-, 3- or 4-pyridyl, quinoxaliny) has afforded mixtures of cis (14a) and trans (14b) isomers of  $[\text{WO}\{\text{SC}(\text{H})\text{C}(\text{Ar})\text{S}\}_2]^{2-}$ , established by  $^1\text{H}$  NMR spectroscopy, but only cis-isomers were crystallized and characterized crystallographically.

Reaction of  $[\text{WO}(\text{bdt})_2]^{2-}$  with one equivalent of  $\text{SiBu}'\text{R}_2\text{Cl}$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ) afforded the ‘desoxo’ complexes  $[\text{W}(\text{OSiR}_2\text{Bu}')(\text{bdt})_2]^-$ . Addition of  $\text{OR}'^-$  ( $\text{R}' = \text{Pr}^i$  or

$\text{Ph}$ ) to  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]$  afforded  $[\text{W}(\text{OR}'(\text{S}_2\text{C}_2\text{Me}_2)_2)]^-$  and reaction of these species with  $\text{Me}_3\text{NO}$  afforded  $[\text{WOOR}'(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$ . With  $\text{EAr}^-$ ,  $[\text{W}(\text{CO})(\text{EAr})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  ( $\text{E} = \text{S}$ ,  $\text{Se}$ ;  $\text{Ar} = 2\text{-adamantyl}$ ,  $\text{Ph}$ ,  $\text{C}_6\text{H}_2\text{-2,4,6-Pr}_3$ ) was formed. Similar reactions with alkoxides and phenolates afforded  $[\text{WO}(\text{ER})(\text{S}_2\text{C}_2\text{Me}_2)_2]^{3-}$  ( $\text{E} = \text{O}$ ,  $\text{R} = \text{Pr}^i$ , 2-adamantyl,  $p\text{-C}_6\text{H}_4\text{X}$ , where  $\text{X} = \text{CN}$ ,  $\text{Br}$ ,  $\text{Me}$ ,  $\text{OMe}$ ,  $\text{NH}_2$ ;  $\text{E} = \text{S}$ ,  $\text{Se}$ ,  $\text{R} = 2\text{-adamantyl}$ ). Treatment of  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]$  with  $\text{O}_2\text{CPh}^-$  gave  $[\text{W}(\text{O}_2\text{CPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$ . The structure of  $[\text{WO}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  and the catalytic center of one DMSO reductase isoenzyme have similar overall stereochemistry and comparable bond lengths. The  $\text{W}^{\text{IV}}$  complex  $[\text{W}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  reacted quantitatively with various substrates  $\text{XO}$  to afford  $[\text{W}^{\text{VI}}\text{O}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  and  $\text{X}$  in second order reactions with associative transition states.

Sodium naphthalenide reduction of  $[\text{W}^{\text{V}}\text{O}(\text{bdt})_2]^-$  afforded a mixture of  $[\text{W}(\text{bdt})_3]^{2-}$  and  $[\text{W}^{\text{IV}}\text{O}(\text{bdt})_2]^{2-}$  which, with  $\text{Me}_3\text{NO}$ , under O-atom transfer afforded  $[\text{W}^{\text{VI}}(\text{O})_2(\text{bdt})_2]^{2-}$ . Reaction of this dioxo species with  $\text{Me}_3\text{SiCl}$  afforded  $[\text{W}^{\text{VI}}\text{OCl}(\text{bdt})_2]^-$ . Reaction of the oxo-chloro complex with  $\text{P}(\text{OEt})_3$  in the absence and presence of  $\text{Bu}'\text{NC}$  afforded  $[\text{W}^{\text{IV}}\{(\text{P}(\text{OEt})_3)_2(\text{bdt})_2\}]$  and  $[\text{W}^{\text{IV}}\text{CNBu}'_2(\text{bdt})_2]$ , both reduction processes, but with  $\text{OBU}'^-$  and  $\text{SPh}^-$   $[\text{W}^{\text{VI}}(\text{O})(\text{OBU}')(\text{bdt})_2]^-$  and  $[\text{W}^{\text{VI}}(\text{O})(\text{SPh})(\text{bdt})_2]^-$  were formed. Reaction of  $[\text{W}^{\text{IV}}\text{O}(\text{bdt})_2]^{2-}$  with  $\text{Me}_3\text{SiCl}$  afforded  $[\text{W}^{\text{IV}}(\text{OSiMe}_3)(\text{bdt})_2]^-$ .

Treatment of  $[\text{W}(\text{CO})_3(\text{NCMe})_3]$  with  $[\text{Ni}(\text{S}_2\text{C}_2\text{R}_2)_2]$  gave the dithiolene complexes  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{R}_2)_2]$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ). Reaction of  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]^{2-}$  with  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]$  afforded the paramagnetic  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]^\cdot$ . The dicarbonyl species  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]^\cdot$  and the related tris(dithiolene) complexes  $[\text{W}(\text{S}_2\text{C}_2\text{Me}_2)_3]^\cdot$  exist as a three-membered electron transfer chain,  $z = 0, -1$ , and  $-2$ , which were interconnected by reversible redox reactions. Members of both series have similar distorted trigonal prismatic structures. As the most oxidized species ( $z = 0$ ) were reduced, the  $\text{M-S}$ ,  $\text{S-C}$ , and  $\text{C-O}$  distances increased, and the  $\text{M-C}$ , chelate ring  $\text{C-C}$ , and  $\nu_{\text{CO}}$  values decreased. Whereas the most oxidized species  $[\text{W}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2]$  and  $[\text{W}(\text{S}_2\text{C}_2\text{Me}_2)_3]$  formally contain  $\text{W}^{\text{IV}}$  and  $\text{W}^{\text{VI}}$ , respectively, the trends in bond lengths and vibrational frequencies, coupled to density functional calculations, established that the redox orbital in these ‘noninnocent’ complexes was predominantly sulfur ligand based, that is, that the electron transfer behavior is largely ligand based.

Crystallographic studies of  $[\text{WO}(\text{bdt})_2]^-$  and  $[\text{WO}(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  established that they had square pyramidal structures. Reaction of  $[\text{W}^{\text{IV}}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  with two

equivalents of benzenethiol or benzene selenol afforded  $[W^V(EPh)_2(S_2C_2Me_2)_2]^-$  ( $E = S$  or  $Se$ ), but when one equivalent of  $Ph_3CSH$  was employed, dinuclear  $[W_2(\mu-S_2(S_2C_2Me_2)_4)]^{2-}$  was formed. This complex could also be generated by reaction of  $[W(CO)_2(S_2C_2Me_2)_2]$  with  $S_2^{2-}$  or the oxidation of  $[W^{IV}S(S_2C_2Me_2)_2]^{2-}$  by iodine. The corresponding dinuclear species  $[W_2(\mu-S_2(S_2C_2Ph_2)_4)]^{2-}$  was obtained by tropylium cation oxidation of  $[WS(S_2C_2Ph_2)_2]^{2-}$ .

Recent crystallographic studies of the active sites in tungsto-enzymes has suggested the possibility of desoxo-tungsten(IV) and mono-oxo-tungsten (VI) bis(dithiolato) centers to which serine molecules might be additionally coordinated. Attempts to mimic the coordination environment around the tungsten atom led to the generation of  $[W^{VI}O(OSiBu^tPh_2)(bdt)_2]^-$  and  $[WO(OPh)(S_2C_2Me_2)_2]^-$  (**15**) by treatment of  $[W(OR)(dithiolato)_2]^-$  precursors with an excess of  $Me_3NO$ , as described above.

Treatment of  $WOCl_4$  with  $Li_2bdt$  or of  $[WO(bdt)_2(OSiBu^tPh_2)]^-$  with  $SiMe_3Cl$  afforded  $[W^{VI}O(bdt)_2Cl]^-$ . Reaction of  $[W(OR)(S_2C_2Me_2)_2]^-$  ( $R = Ph$  or  $SiBu^tPh_2$ ), which formally contains W(IV), with dibenzyltrisulfide or  $(Me_3Si)_2S$  afforded the sulfido complexes  $[W^{VI}S(bdt)(OR)]^-$ , an oxidative addition formally generating W(VI) species.

Addition of trimethylamine *N*-oxide to  $[W^{IV}O(bdt)_2]^-$  and to  $[WO(S_2C_2Me_2)_2]^-$  afforded the W(VI) complexes  $[WO_2(bdt)_2]^{2-}$  and  $[WO_2(S_2C_2Me_2)_2]^{2-}$ , in which the oxo groups were mutually *cis*. Because of *trans* influences, the W–S bonds *trans* to the oxo groups in  $[WO_2(bdt)_2]^{2-}$  (as the  $Et_4N^+$  salt) were longer (2.60 Å) than those which were *cis* (2.43 Å). Reaction of aqueous  $WO_4^{2-}$  with  $mnt^{2-}$  in the presence of an excess of  $HSO_3^-$  (*pH* 5.5) followed by addition of acetic acid afforded the structurally similar  $[WO_2(mnt)_2]^{2-}$ .

## 5.2 Thiolato Complexes

Addition of  $RSH$  ( $R = Bu^t, Ph$ ) to  $[W(CO)_3(phen)(NCEt)]$  afforded  $[W(CO)_3(phen)(Bu^tSH)]$  or  $[W(CO)_3H(phen)(SPh)]$ .  $[W(CO)_5(SPh)]^-$ , obtained by reaction of  $[W(CO)_5$

$(thf)]$  with  $(SPh)^-$ , converted slowly to  $[W(\mu-S)_2(CO)_8]^{2-}$  on gentle heating.

Addition of  $PhSSPh$  to  $[W(CO)_3(PPr^i)_3]_2$  afforded the paramagnetic  $W^I$  complex  $[W(CO)_3(PPr^i)_2(SPh)]$ .

Reaction of  $[W^{IV}H(tipt)_3(PMe_2Ph)_2]$  with  $CNMe$  in *thf* afforded *cis*- $[W^{II}(CNMe)_4(tipt)_2]$  ( $tipt = SC_6H_2Pr^i_{3-2,4,6}$ ). Similarly, reaction of  $[WH(tipt)_3(PMe_2Ph)_2]$  with  $CO$  led to loss of thiol and formation of  $[W(CO)_2(PMe_2Ph)_2](tipt)_2$ . The dicarbonyl was isolated as two isomers (green 90%; red 10%), and variable-temperature  $^1H$  NMR spectroscopy indicated that they were fluxional and interconverted in solution. The structure of the green isomer of the analogous  $[W(CO)_2(PMe_2Ph)_2(SC_6H_2Me_{3-2,4,6})_2]$  revealed that it had a twisted trigonal prismatic geometry. The selenolate  $[W(CO)_2(PMe_2Ph)_2(SeC_6H_3Pr^i_{2,2})_2]$  was obtained similarly and had a slightly distorted trigonal prismatic geometry.

Reaction of  $[W(CO)_3(PEt_3)_2I_2]$  with  $SPh^-$  or  $[S(CH_2)_nS]^{2-}$  ( $n = 2, 3$ ) afforded the octahedral species  $[W^{II}(CO)_2(PEt_3)_2(SPh)_2]$  and  $[W^{II}(CO)_2(PEt_3)_2[S(CH_2)_nS]]$ . The  $W(0)$  complex  $[W(CO)_3(phen)(NCEt)]$  underwent oxidative addition with dialkyl and diaryl disulfides forming  $[W^{II}CO_2(phen)(SR)_2]$  ( $R = Ph, CH_2Ph, Me, Bu^t$ ).  $[W(CO)_2(phen)(SPh)_2]$  reacted with  $P(OMe)_3$  giving  $[W(CO)\{P(OMe)_3\}(phen)(SPh)_2]$  and the X-ray structures of  $[W(CO)_2(phen)(SPh)_2]$  and  $[W(CO)\{P(OMe)_3\}(phen)(SPh)_2]$  showed that they were both octahedral, with the phenylthiolato ligands in *trans* positions. Both molecules reacted with  $SO_2$  giving  $[W(CO)(phen)(SPh)_2](\kappa^2-SO_2)]$ . The coordinated S–O bond was long (1.58 Å) and could be cleaved to give  $[WO_2(phen)(SPh)_2]$  (*cis* dioxo groups, *trans* thiolato groups), with loss of  $CO$  and sulfur.

The tetrathiolate  $[W^{IV}(SBu^t)_4]$  was obtained by reaction of  $[WCl_4(SEt_2)_2]$  with  $SBu^t^-$ . Reaction of *cis*- $W(N_2)_2(PMe_2Ph)_4]$  with  $Bu^tSH$  in *thf* afforded the dinuclear species  $[W(SBu^t)_2(PMe_2Ph)_2(\mu-S)_2]$  (**16**). Reaction of  $[W(CO)_3I_2(NCMe)]$  with the potential  $NS_3$ -podand ligand  $N(CH_2CH_2SH)_3$  afforded, in the presence of  $NEt_3$ , the dinuclear species  $[W^{IV}(SCH_2CH_2)_3N]_2\{\mu-SCH_2CH_2N(CH_2CH_2SH)_2\}_2]$ .

The square-planar ethanedithiolato complexes  $[W^{VO}(SCH_2CH_2S)_2]^-$  were obtained by a ligand exchange reaction involving  $[WO(SPh)_4]^-$ . The X-ray crystallographic examination of  $[W^{VO}(SC_6H-2,3,5,6-Me_4)_4]^-$  revealed that it too was nearly square planar.

### 5.3 Thioether Complexes

The cyclic polythioether complex  $[\text{W}(\text{CO})_4\text{L}]$  ( $\text{L} = 2,5,8,11\text{-tetrathia}[12](2,5)\text{thiophenophane}$ ) was prepared by UV irradiation of  $[\text{W}(\text{CO})_6]$  in the presence of the ligand in thf. Variable-temperature  $^1\text{H}$  NMR studies showed that this species was fluxional, and the derived molecular structure indicated  $\kappa^2\text{-L-S}^5\text{S}^8$  coordination (**17**). The thioether-bridged complexes  $[\{\text{W}(\text{CO})_4\}_2\text{L}]$  (**18**), where L is the hexakis(alkylsulfanylmethyl)benzene,  $\text{C}_6(\text{CH}_2\text{SR})_6$  ( $\text{R} = \text{C}_5\text{H}_{11}$ ,  $\text{Pr}^n$ ) were obtained by reaction of  $[\text{W}(\text{CO})_4(\text{NCMe})_2]$  with the appropriate thioether. Reaction of  $[\text{W}(\text{CO})_4(\text{tmpa})]$  ( $\text{tmpa} = N,N,N',N'$ -tetramethyl-1,3-propanediamine) with 1,5-diselenacyclooctane ( $[\text{8}] \text{aneSe}_2$ ) gave the cis-disubstituted produce  $[\text{W}(\text{CO})_4\{[\text{8}] \text{aneSe}_2\}]$ .

(17)

(18)

### 5.4 Sulfides, Selenides and, Tellurides

Reaction of  $\text{Se}_4(\text{AsF}_6)_2$  or  $\text{Se}_8(\text{AsF}_6)_2$  with  $[\text{W}(\text{CO})_6]$  in liquid  $\text{SO}_2$  afforded the diamagnetic  $[\text{W}_2(\text{CO})_{10}\text{Se}_4][\text{AsF}_6]_2$  (**19**), which contained a  $\mu\text{-Se}_4^{+}$  moiety. The short  $\text{Se}\cdots\text{Se}$  bond lengths (2.29 Å) are close to those found in gaseous  $\text{Se}_2$  (2.19 Å), while the longer  $\text{Se}-\text{Se}$  bonds suggested that the complex should be formulated as containing two  $\{\text{W}(\text{CO})_5(\kappa^2\text{-Se}_2)\}^+$  groups.

Treatment of  $[\text{W}(\text{CO})_6]$  with  $\text{Te}_4(\text{SbF}_6)_2$  in  $\text{SO}_2/\text{AsF}_3$  afforded  $[\text{W}(\text{CO})_4(\eta^3\text{-Te}_3)][\text{SbF}_6]_2$  (**20**). The molecular structure of this species confirmed the 'piano-stool' geometry, and the triangular  $\text{Te}_3^{2+}$  group. Reaction of  $[\text{W}(\text{CO})_6]$  with  $\text{K}_2\text{Te}_4$  afforded  $[\text{W}(\text{CO})_4(\kappa^2\text{-Te}_4)]$ , which contained a five-membered  $\text{WTe}_4$  chelate ring.

Reaction of  $[\text{W}(\text{CO})_5(\text{thf})]$  with  $[\text{Fe}(\text{CO})_3\text{I}_2(\text{TePh}_2)]$  and with  $\text{Bu}^t_3\text{P}=\text{Te}$  caused replacement of the thf and

(19)

(20)

formation of the tellurium adducts  $[\text{W}(\text{CO})_5(\text{TePh}_2)]$  and  $[\text{W}(\text{CO})_5(\text{Te}=\text{P}^t\text{Bu}_3)]$ , respectively.

The monomeric tetraselenide ion  $[\text{W}^{\text{IV}}(\text{E})(\text{Se}_4)_2]^{2-}$  ( $\text{E} = \text{O}, \text{S}, \text{Se}$ ) was prepared by reaction of  $[\text{WSe}_4]^{2-}$  with  $\text{Se}_8$ ,  $\text{SeS}_2$ , or  $\text{Se}_4(\text{NC}_5\text{H}_{10})_2$  in dmf, respectively. Tungsten hexachloride,  $\text{WCl}_4$ , or  $\text{WOCl}_4$  reacted with polytelluride ions  $\text{Te}_3^{2-}$ ,  $\text{Te}_4^{2-}$ , and  $\text{Te}_5^{2-}$  in dmf giving  $\text{W}^{\text{IV}}\text{O}(\kappa^2\text{-Te}_4)_2]^{2-}$ .

Reaction of  $[\text{WSe}_4]^{2-}$  with phosphorus selenide glass, ' $\text{P}_2\text{Se}_4$ ', afforded  $[\text{W}^{\text{IV}}\text{Se}(\text{PSe}_2)(\text{PSe}_4)]^{2-}$  (**21**), which contained  $\text{PSe}_4^{3-}$  and the trihapto hetero-allylic  $\text{PSe}_2^{2-}$  group. Treatment of  $[\text{W}(\text{CO})_6]$  or  $[\text{W}(\text{CO})_2(\text{As}_2\text{Se}_3)_2]^{2-}$  with  $\text{As}_4\text{Se}_4$  and  $\text{K}_2\text{Se}_3$  afforded  $[\text{W}(\text{AsSe}_5)_2]^{2-}$  (**22**).  $[\text{W}(\text{CO})_2(\text{As}_3\text{Se}_3)_2]^{2-}$  (**23**) was generated by reaction of  $[\text{W}(\text{CO})_6]$  with  $\text{As}_4\text{Se}_6^{2-}$ , and its reaction with red selenium converted it into  $[\text{W}(\text{AsSe}_5)_2]^{2-}$ .

(21)

(22)

Treatment of  $[\text{W}(\text{PMe}_3)_6]$ , better formulated as  $[\text{W}(\kappa^2\text{-CH}_2\text{PMe}_2)_2\text{H}_2(\text{PMe}_3)_4]$ , with  $\text{H}_2\text{E}$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ) or elemental tellurium afforded  $\text{trans-}[\text{W}(\text{E})_2(\text{PMe}_3)_4]$  ( $\text{E} = \text{S}, \text{Se}$  or  $\text{Te}$ ). These reactions proceeded through the intermediate  $[\text{W}(\text{E})(\text{H}_2)(\text{PMe}_3)_4]$ , the species containing  $\text{E} = \text{Se}$  being characterized crystallographically. The species

$[\text{W}(\text{PMe}_3)_4(\text{H})_2(\text{SH})_2]$  could also be detected. Reaction of the dihydride  $[\text{WH}_2(\text{PMe}_3)_4]$  with elemental tellurium afforded  $[\text{WH}_2(\text{PMe}_3)_4(\kappa^2\text{-Te}_2)_2]$ , from which  $[\text{W}(\text{Te})_2(\text{PMe}_3)_4]$  could be obtained by oxidative cleavage of the Te-Te bonds.

Reaction of *trans*- $\text{W}(\text{E})_2(\text{PMe}_3)_4$  (E = S or Se) with isonitriles,  $\text{CNR}$  (R = alkyl, aryl), afforded all-*trans*- $[\text{W}(\text{E})_2(\text{CNR})_2(\text{PMe}_3)_2]$  whereas reaction of  $[\text{W}(\text{Te})_2(\text{PMe}_3)_4]$  with  $\text{CNBu}^t$  afforded  $[\text{W}(\text{CNBu}^t)_4(\text{PMe}_3)(\kappa^2\text{-Te}_2)]$  (24).

Treatment of  $[\text{WO}_4]^{2-}$  with  $\text{NH}_4\text{SCN}$  in aqueous HCl gave oxotungsten(V) species, and reaction of this solution with polysulfide ion afforded  $[(\text{S}_4)(\text{O})\text{W}(\mu\text{-S})_2\text{W}(\text{O})(\text{S}_2)]^{2-}$  and the symmetrical species  $[\{\text{WO}(\text{S}_4)\}_2\mu\text{-S}_2]^{2-}$ .

Relatively few tungsten(VI) selenide or telluride species are known. Treatment of *trans*- $[\text{W}^{\text{VI}}\text{E}_2(\text{PMe}_3)_4]$  (E = S, Se, Te) with aldehydes afforded the metalla-oxirane derivative  $[\text{W}^{\text{VI}}\text{E}_2(\text{PMe}_3)_2(\kappa^2\text{-OCHR})]$  (25). Reaction of species containing  $\{\text{WO}\}^{3+}$  with  $(\text{NH}_4)_2\text{S}_x$  in the presence of 2,2'-dipyridyl (bipy) afforded the mononuclear species  $[\text{WO}(\kappa^2\text{-S}_2)_2(\text{bipy})]$  and reaction of  $[\text{WO}_2\text{S}_2]^{2-}$  with elemental sulfur and hydrazinium hydrochloride afforded  $[\{\text{WO}(\kappa^2\text{-S}_2)_2\}_2(\mu_2\text{-S}_7)(\mu_2\text{-NH}_2\text{NH}_2)]$  (26).

## 5.5 Dithioacid, Dithiocarbamate, Dithiophosphate, and Related Complexes

Elimination of HCl from  $[\text{W}(\text{CO})_2(\text{H})\text{Cl}(\text{PMe}_3)_2]$  upon treatment with  $\text{CS}_2$  and  $\text{PMe}_3$  afforded  $[\text{W}(\text{CO})_2(\text{PMe}_3)_2](\kappa^3\text{-S,S',C-S}_2\text{CPMe}_3)$ . Treatment of this complex with  $\text{HBF}_4$  generated a dithioformato species  $[\text{W}(\text{CO})_2(\text{PMe}_3)_2\{\kappa^2\text{-S}_2\text{C}(\text{H})\text{PMe}_3\}]^+$  and addition of MeI gave the analogous  $[\text{W}(\text{CO})_2(\text{PMe}_3)_2\{\kappa^2\text{-S}_2\text{C}(\text{SMe})\text{PMe}_3\}]^+$ .

The tungsten carbyne complex  $[\text{W}(\equiv\text{CPh})(\text{CO})_2(\text{py})_2\text{Cl}]$  reacted with  $(\text{S}_2\text{CNEt}_2)^-$  giving  $[\text{W}^{\text{II}}(\text{CO})(\eta^2\text{-SCHPh})(\kappa^2\text{-C,S-SCNEt}_2)]$ , which was regarded as containing a neutral dihapto thiobenzaldehyde group. The complex could equally well be regarded as a metallacyclic  $\text{W}^{\text{IV}}$  complex binding  $(\text{SCHPh})^{2-}$ .

Reaction of  $[\text{WOCl}_2(\text{PMe}_3)_2]$  with potassium *O*-alkyl xanthates,  $\text{KS}_2\text{COR}$  (R = Me, Et,  $\text{Pr}^i$ ) in thf afforded two isomers of  $[\text{W}^{\text{IV}}\text{O}\{\text{S}_2\text{C}(\text{PMe}_3)(\text{OR})\text{-S,S'}\}(\text{S}_2\text{COR-S,S'C})]$  (27a) and (27b). These two isomers were identified in solution, and the structure of (27a) was confirmed for a molybdenum analog (R =  $\text{Pr}^i$ ). It was suggested that the zwitterionic ligand  $^-\text{S}_2\text{C}^-(^+\text{PMe}_3)\text{OR}$  was generated by nucleophilic attack of trimethylphosphine on the C atom of the  $\text{CS}_2$  moiety.

Reductive desulfurization of  $[\text{WS}(\text{S}_2)(\text{S}_2\text{CNEt}_2)_2]$  using  $\text{SiMe}_3\text{I}$  afforded  $\text{W}^{\text{V}}(\mu\text{-S}_2)_2(\text{S}_2\text{CNEt}_2)_4[\text{I}(\text{I}_3)]$ . Reaction of  $[\text{W}(\text{S}_2\text{CNR}_2)_4]^+$  with  $\text{LiTCNQ}$  gave  $[\text{W}(\text{S}_2\text{CNEt}_2)_4][\text{TCNQ}]$ .

## 6 COMPLEXES WITH N-DONOR ATOMS

### 6.1 Nitrido Complexes

Reaction of  $\text{WCl}_6$  with  $\text{Me}_3\text{SiNPhMePh}$  afforded the mixed-valence  $\text{W}^{\text{V}}_2\text{W}^{\text{VI}}_2$  species  $[\text{PClMePh}_2]_2[\text{W}_4\text{N}_2\text{Cl}_{18}]$  (28). This species contains two  $\text{W}^{\text{VI}}$  components  $[\text{WNC}_4]^-$  and

two neutral  $\text{WCl}_5$  fragments. Two distinct W–N bonds were detected in the crystal structure, one a triple bond (1.69 Å) and the other a single bond (2.06 Å), with an almost linear W–N–W bond angle (178°).

Reaction of  $[\text{W}^{\text{III}}_2(\text{O}^t\text{Bu}')_6]$  with acetonitrile or benzonitrile afforded alkylidyne and nitrido complexes:  $[\{\text{W}^{\text{VI}}(\text{N})(\text{O}^t\text{Bu}')_3\}_n]$  was polymeric, the terminal nitrido group interacting with neighboring W atoms via a weak donor bond. While  $[\text{W}_2(\text{OCH}_2\text{CH}_2\text{CF}_3)_6]$  did not react with acetonitrile, with benzonitrile the trinuclear triangular species  $[\{\text{W}(\text{N})(\text{OCH}_2\text{CH}_2\text{CF}_3)_3\}_3]$ , having  $\mu$ -nitrido bridges, was formed. The W–N bond lengths alternate from 1.72 Å to 2.14 Å.

## 6.2 Imido Complexes

Reaction of the zwitterionic  $[\text{W}(\text{CO})_5\{\text{NPhNPhC}(\text{OMe})\text{Ph}\}]$  with  $\text{PCl}_5$ ,  $\text{Br}_2$ , or  $\text{I}_2$  gave the imido complex  $[\{\text{W}^{\text{IV}}(\text{NPh})_2(\text{CO})_2\text{X}(\mu\text{-X})_2\}]$ . This dinuclear species reacted with donor ligands ( $\text{L}$  = pyridine,  $\text{PR}_3$ , or  $\text{NCMe}$ ) giving  $[\text{WNPh})_2(\text{CO})_2(\text{LX}_2)]$ .

The dinuclear complex containing a bridging diimido ligand  $[\{\text{W}^{\text{IV}}(\text{CO})(\text{PMePh}_2)_2\text{Cl}_2\}_2(\mu\text{-NHC}_6\text{H}_4\text{NH-}p)]$  was obtained by the reaction of  $[\text{WCl}_2(\text{PMePh}_2)_4]$  with the diisocyanate 1,4- $\text{C}_6\text{H}_4(\text{NCO})_2$ . A range of analogous complexes  $[\{\text{W}(\text{CO})(\{\text{PMePh}_2\}_2\text{Cl}_2)_2(\mu\text{-N-X-N})\}]$ , where

N–X–N =  $p$ -N- $o$ - $\text{MeC}_6\text{H}_3\text{N}$ ,  $p$ -N( $o$ - $\text{MeOC}_6\text{H}_3\text{C}_6\text{H}_3$  OMe- $o$ )N, 1,5- $\text{NC}_{10}\text{H}_6\text{N}$ , or  $m$ - $\text{NC}_6\text{H}_4\text{N}$ , were prepared similarly and several complexes were investigated crystallographically. In all of these species, the  $\text{PMePh}_2$  groups are mutually trans and the chloride ions cis. Electrochemical studies established that all complexes underwent two oxidation processes at low temperatures, indicating weak electronic communication between the metal centers. Only the species containing  $p$ - $\text{NC}_6\text{H}_4\text{N}$  and  $p$ -N- $o$ - $\text{MeC}_6\text{H}_3\text{N}$  exhibited well-defined reduction behavior, undergoing two one-electron reduction processes, the remainder of the complexes exhibiting irreversible reduction behavior.

The silylimido complex  $[\text{W}(\text{NSiMe}_3)\text{Cl}_2(\text{PMe}_3)_3]$  was prepared by reaction of  $\text{WCl}_2(\text{PMe}_3)_4$  with  $\text{Me}_3\text{SiN}_3$ .

Treatment of  $[\text{WCl}_4(\text{SEt}_2)_2]$  with the tetradentate triamidoamine ligand  $\text{N}(\text{CH}_2\text{CH}_2\text{NHC}_6\text{F}_5)_3$  afforded  $[\text{W}^{\text{IV}}\{\text{N}(\text{C}_6$

$\text{F}_5)\text{CH}_2\text{CH}_2)_3\text{N}\}\text{Cl}]$ , which had a distorted trigonal bipyramidal structure.

Reaction of  $[\text{W}(\text{NPh})(\eta^4\text{-C}_6\text{H}_5\text{Pr}^n)\{\text{o-C}_6\text{H}_4(\text{NSiMe}_3)_2\}]$  with pyridine, 4-picoline, or quinoline ( $\text{L}$ ) or reduction of  $[\text{W}(\text{NPh})\{\text{o-C}_6\text{H}_4(\text{NSiMe}_3)_2\}\text{Cl}_2]$  with sodium in the presence of  $\text{L}$  afforded  $[\text{W}^{\text{IV}}(\text{NPh})\{\text{o-C}_6\text{H}_4(\text{NSiMe}_3)_2\}\text{L}_2]$  (**29**). This complex reacted with CO or  $\text{PMe}_3$  ( $\text{L}'$ ) in toluene to form the 6-coordinate *trans*- $[\text{W}(\text{NPh})\{\text{o-C}_6\text{H}_4(\text{NSiMe}_3)_2\}\text{L}_2\text{L}']$ .

Addition of  $\text{LiOC}_6\text{H}_2(\text{CH}_2\text{NMe}_2)_2$ -2,6-Me-4 to  $[\text{W}(\text{NPh})\text{Cl}_4(\text{OEt}_2)]$  resulted in displacement of the ether and formation of  $[\text{W}^{\text{VI}}(\text{NPh})\text{Cl}_3\{\text{OC}_6\text{H}_2(\text{CH}_2\text{NMe}_2)_2\text{Me}\}]$  (**30**), in which one of the two  $\text{NMe}_2$  groups is coordinated trans to the phenylimido ligand. Oxidation of  $[\text{W}(\text{NPR}_3)\text{Cl}_5]$  ( $\text{R}$  = Me or Ph), or addition of  $\text{R}_3\text{PO}$  to  $[\{\text{W}(\text{NCl})\text{Cl}_4\}_2]$ , afforded  $[\text{W}(\text{NCl})\text{Cl}_4(\text{OPR}_3)]$ .

Treatment of  $[\text{W}(\text{NAr})\text{Cl}_4(\text{thf})]$  ( $\text{Ar}$  = 2,6- $\text{Pr}^i_2\text{C}_6\text{H}_3$ ) with two equivalents of  $\text{Me}_3\text{SiNHar}$  in thf gave  $[\text{W}(\text{NAr})_2\text{Cl}_2(\text{thf})_2]$  and this dichloride reacted with  $\text{LiNHar}$  giving tetrahedral  $[\text{W}(\text{NAr})_3\text{Cl}]^-$ .

Deprotonation of  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)_2]$  by  $\text{LiMe}$  afforded dimeric  $\text{Li}_2[\text{W}(\text{NBu}^t)_4]$ , whose crystal-structure determination revealed that it should be formulated as  $[\text{Li}_4\text{W}_2(\text{NBu}^t)_8]$  (**31**). The bridging  $\text{NBu}^t$  groups are coordinated as amido rather than imido ligands, and the terminal  $\text{NBu}^t$  group exhibits a reasonably short  $\text{W}=\text{N}$  bond (1.72 Å). This species reacted with the Lewis acids  $\text{AlCl}_3$ ,  $\text{GaCl}_3$ , and  $\text{AlMe}_3$  giving  $[\{\text{W}(\mu\text{-NBu}^t)_2\text{M}'\text{X}_2\}_2]$  ( $\text{M}'$  = Al or Ga,  $\text{X}$  = Cl or Me, e.g. (**32**)).

Protonation of  $\text{Li}_2[\text{W}(\text{NBu}^t)_4]$  in ether gave initially  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)_2]$ , but further acid ( $\text{CF}_3\text{SO}_3\text{H}$ ,  $\text{CF}_3\text{CO}_2\text{H}$ )

gave octahedral species such as  $[\text{W}(\text{NBu}^t)_2(\text{NH}_2\text{Bu}^t)_2\text{X}_2]$  ( $\text{X} = \text{OSO}_2\text{CF}_3$ ,  $\text{OC}(\text{O})\text{CF}_3$ ). With  $\text{HBF}_4$ , two species,  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)(\text{NH}_2\text{Bu}^t)][\text{BF}_4]$  and  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)(\text{NH}_2\text{Bu}^t)(\text{F}_2\text{BF}_2)]$ , were isolated, whereas with  $\text{HCl}$ , only  $[\{\text{W}(\text{NBu}^t)_2(\text{NH}_2\text{Bu}^t)\text{Cl}\}_2(\mu\text{-Cl})_2]$  was formed. Treatment of  $[\text{W}(\text{NR})\text{Cl}_4\text{L}]$  ( $\text{R} = \text{Et}$ ,  $\text{L} = \text{nothing}$ ;  $\text{R} = \text{C}_6\text{H}_4\text{Me-4}$ ,  $\text{L} = \text{OEt}_2$ ) with  $\text{N}(\text{SiMe}_3)_3$  in a 2:1 ratio afforded the hexanuclear species  $[\{\text{W}_2(\mu_2\text{-N})(\text{NR})_2\text{Cl}_5\}_3]$  (33). Within each  $(\text{RN})\text{W}(\mu\text{-N})\text{W}(\text{NR})$  group, the two imido groups have nearly orthogonal orientations that maximize  $\text{W-N}$   $\pi$ -bonding.

Reaction of  $[\text{W}^{\text{II}}\text{Cl}_2\text{L}_4]$  ( $\text{L} = \text{PMe}_3$  or  $\text{PMePh}_2$ ) with one equivalent of  $\text{Me}_3\text{SiN}_3$  gave the bis(silylimido) complex  $[\text{W}^{\text{VI}}(\text{NSiMe}_3)_2\text{Cl}_2\text{L}_3]$ . When two equivalents of  $\text{Me}_3\text{SiN}_3$  were used, oxidative replacement afforded the five-coordinate mono(silylimido) complex  $[\text{W}(\text{NSiMe}_3)\text{Cl}_2(\text{PMePh}_2)_2]$ , which has a trigonal bipyramidal geometry, with cis equatorial imido ligands and short  $\text{W-N}$  bonds (1.70 Å).

Treatment of  $[\text{W}(\text{NAr})_2(\text{PMe}_2\text{Ph})_2]$  ( $\text{Ar} = 2,6\text{-Pr}^i_2\text{C}_6\text{H}_3$ ) with acetone in pentane afforded  $[\text{W}(\text{NAr})_2(\text{PMe}_2\text{Ph})(\kappa^2\text{-OCMe}_2)]$ . The long  $\text{C-O}$  bond (1.39 Å) in, and spectroscopic properties of, this complex were thought to be consistent with an oxo-metallopropane  $\text{W}^{\text{VI}}$  arrangement (34). Tetradentate Schiff bases derived by condensation of 1-hydroxy-2-benzaldehydes with alkane diamines reacted with  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)_2]$  giving six-coordinate species such as (35), which contained *cis*-butylimido groups. Reaction of  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)_2]$  with  $\{\text{HOSiPh}_2\}_2\text{O}$  afforded an imido metallosiloxane  $[\text{W}(\text{NBu}^t)(\text{NH}_2\text{Bu}^t)(\text{OSiPh}_2\text{OSiPh}_2\text{O})_2]$ , in

which the two N atoms were trans to each other, and the two  $\text{Bu}^t$  groups were distinguishable by  $^1\text{H}$  NMR spectroscopy.

Treatment of  $[\text{W}(\text{NBu}^t)_2(\text{NHBu}^t)_2]$  with a  $\text{Me}_2\text{NP}$ -modified calix[5]arene afforded (36), in which the  $\text{W}\cdots\text{P}$  bond was relatively weak. The amido ligand was displaced by triflic acid, the  $\text{W-P}$  bond in the resulting triflate species becoming stronger.

### 6.3 Amido Complexes

Treatment of  $\text{W}(\text{CO})_5(\text{thf})$  with  $o\text{-}[\text{OC}_6\text{H}_4\text{NH}_2]^-$  and  $o\text{-C}_6\text{H}_4(\text{NH}_2)_2$  in the presence of deprotonating agents afforded  $[\text{W}(\text{CO})_3\{o\text{-O}(\text{NH})\text{C}_6\text{H}_4\}]^-$  and  $[\text{W}(\text{CO})_3\{o\text{-(NH}_2\text{)C}_6\text{H}_4\}]^-$ , which had trigonal bipyramidal structures. Reaction of 2-aminopyridine (2-ampH) with  $[\text{W}(\text{CO})_5(\text{thf})]$  gave

$[\text{W}(\text{CO})_5(2\text{-ampH})]$ , which was deprotonated by  $\text{NAH}$  giving dinuclear  $[\{\text{W}(\text{CO})_4(\mu\text{-}2\text{-amp})\}_2]$  and mononuclear  $[\text{W}(\text{CO})_5(\kappa^1\text{-}2\text{-amp})]^-$ , the latter stabilized by a  $\{\text{Na}^+\text{-crown ether}\}$  counter-cation.

Reaction of  $[\text{W}(\text{NSiMe}_3)\text{Cl}_2(\text{PMe}_3)_3]$  with  $\text{PCl}_2\text{RR}'_2$  ( $\text{R} = \text{R}' = \text{Me}$  or  $\text{R} = \text{Me}$ ,  $\text{R}' = \text{Ph}$ ) afforded the diamagnetic phospho-aminato species  $[\text{W}^{\text{IV}}\text{N}=\text{PR}_3]\text{Cl}_2(\text{PMe}_3)_3\text{Cl}$ . Treatment of  $\text{WCl}_4$  with  $\text{NR}_2(\text{SiMe}_3)$  afforded *fac*- $[\text{WCl}_3(\text{NR}_2)_3]$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ , or pyrrolidine). Reaction of  $[\text{W}(\text{NSiMe}_3)\text{Cl}_2(\text{PMe}_3)_3]$  with  $\text{Cl}_2$  at  $-196^\circ\text{C}$ , followed by warming to room temperature, caused elimination of  $\text{Me}_3\text{SiCl}$  and  $\text{Me}_3\text{PCl}_2$ , the speed of the warm-up procedure determining the product. By these procedures, the phosphoramino complexes  $[\text{W}(\text{N}=\text{PMe}_3)\text{Cl}_5]$  and  $[\text{W}(\text{N}=\text{PMe}_3)\text{Cl}_4(\text{PMe}_3)]$  were formed. Stoichiometric reaction of  $\text{WCl}_6$  with one or two equivalents of  $\text{Cl}_3\text{P}=\text{NSiMe}_3$  afforded  $[\text{W}(\text{NPCl}_3)\text{Cl}_5]$  and  $[\{\text{W}(\text{N}=\text{PCl}_3)\text{Cl}_4\}_2]$ . Reaction of  $[\text{W}(\text{N}=\text{PCl}_3)\text{Cl}_5]$  with  $\text{GaCl}_3$  gave  $[\text{W}(\text{N}=\text{PCl}_3)\text{WCl}_4][\text{GaCl}_4]$ , in which a chlorine atom of the  $[\text{GaCl}_4]^-$  ion is weakly coordinated to the tungsten trans to in aminato group, making W six-coordinate.

Reaction of lithium salts of pyridino-amido ligands  $\text{LiN}(\text{SiMe}_3)(2\text{-C}_5\text{H}_3\text{N-6-Me})$  and  $\text{LiN}(\text{SiBu}^t\text{Me}_2)(2\text{-C}_5\text{H}_3\text{N-6-Me})$  with  $[\text{WO}_2\text{Cl}_2(\text{dme})]$  ( $\text{dme} = 1,2\text{-dimethoxyethane}$ ) gave *cis*- $\text{W}^{\text{VI}}\text{O}_2\{\text{N}(\text{SiR}_3)\text{C}_5\text{H}_3\text{MeN}\}_2$  (**37**).

Reaction of the tungsten(IV) complex  $[\text{W}(\text{NPh})\{o\text{-(Me}_3\text{SiN)}_2\text{C}_6\text{H}_4\}(\text{py})_2]$  with two equivalents of thiophene gave the *S,C*-chelated species  $[\text{W}^{\text{VI}}(\text{NPh})\{o\text{-(Me}_3\text{SiN)}_2\text{C}_6\text{H}_4\}(\text{SC}_4\text{H}_4)]$  (**38**).

Treatment of  $\text{Li}_2[\text{W}(\text{NBu}^t)_4]$  with  $\text{PhSCl}$  gave the sulfenamido complex  $[\text{W}(\text{NBu}^t)_2(\kappa^2\text{-PhSNBu}^t)_2]$  (**39**), which has a distorted bicapped tetrahedral geometry.

Treatment of  $[\text{W}(\text{NPh})\text{Cl}_4]$  with one equivalent of methanol afforded  $[\text{W}(\text{NPh})\text{Cl}_3\text{OMe}]$ , which reacted further with  $\text{LiNMe}_2$  to give  $[\text{W}(\text{NPh})(\text{NMe}_2)_4]$ .

## 6.4 Hydrazido Complexes

Reaction of lithium trimethylsilyldiazomethanide with  $[\text{W}(\text{CO})_5(\text{PPh}_3)]$  in the presence of  $\text{Me}_3\text{SiCl}$  afforded  $[\text{W}(\text{CO})_4(\text{PPh}_3)\{\kappa^1\text{-NNC}(\text{SiMe}_3)_2\}]$  (**40**). The  $\text{W-N}$  bond is long ( $2.16 \text{ \AA}$ ) and the  $\text{N=N}$  ( $1.17 \text{ \AA}$ ) and  $\text{N-C}$  ( $1.343 \text{ \AA}$ ) distances are intermediate between double and triple, and single and double bonds, respectively. Treatment of  $[\text{W}(\text{CO})_5(=\text{NNMe}_2)]$  with *dppe* afforded  $[\text{W}(\text{CO})_3(\text{dppe})(=\text{NNMe}_2)]$ , in which the  $\text{W=N-N}$  group is bent.

The arylation of  $[\text{WCl}_4(\text{dme})]$  with mesityl magnesium bromide under nitrogen afforded the dinuclear  $\text{W}^{\text{III}}$  species  $[\{\text{W}_2(\text{mes})_3\text{Cl}\}_2(\mu\text{-N}_2)]$  ( $\text{mes} = 2,4,6\text{-Me}_3\text{C}_6\text{H}_2$ ), a species which could be regarded as containing the bridging  $\text{N}_2^{4-}$  group. Further addition of magnesium under nitrogen and under thf or mixtures of thf and dioxane afforded tri and tetranuclear species,  $[\text{Cl}(\text{mes})_3\text{W}(\text{N=N})\text{W}(\text{mes})_3(\text{N=N})\text{W}(\text{mes})_3\text{Cl}]^-$  and  $[\text{Cl}(\text{mes})_3\text{W}(\text{N=N})\text{W}(\text{mes})_3(\text{N=N})\text{W}(\text{mes})_3(\text{N=N})\text{W}(\text{mes})_3\text{Cl}]^{2-}$ .

Reaction of  $\text{WCl}_6$  with  $\text{Ph}_2\text{NNH}_2\cdot\text{HCl}$  afforded  $[\text{W}^{\text{VI}}(\text{NNPh}_2)\text{Cl}_4]$ , which on  $\text{Na/Hg}$  reduction in the presence of  $\text{PMe}_2\text{Ph}$ , afforded  $[\text{W}^{\text{IV}}(\text{NNPh}_2)(\text{PMe}_2\text{Ph})_2\text{Cl}_2]$ . This complex reacted with  $\text{HCl}$  or water to generate ammonia and diphenylamine.

Reaction of  $[\text{W}(\text{NNH}_2)(\text{dppe})_2\text{F}]^+$  ( $\text{dppe} = \text{bis}(\text{diphenylphosphine})\text{ethane}$ ) with 2,5-dimethoxytetrahydrofuran under acid-catalyzed conditions afforded the pyrrolylimido complex (**41**). However, when the same reaction was carried out with the corresponding 2,5-dihydrofuran, the kinetic product formed initially (**42**), slowly isomerizing to the thermodynamically more stable (**43**).

In related reactions, *cis,mer*- $[\text{W}(\text{NHNH}_2)(\text{PMe}_2\text{Ph})_3\text{X}_2]$  ( $\text{X} = \text{Cl}$  or  $\text{Br}$ ) with phthalaldehyde afforded (**44**).

(41)

(42)

(43)

(44)

Treatment of  $[\text{W}(\text{N}_2)_2(\text{PMe}_2\text{Ph})_4]$  with HCl under CO afforded  $[\text{W}^{\text{IV}}(\text{NNH}_2)(\text{CO})(\text{PMe}_2\text{Ph}_2)\text{Cl}_2]$ , which reacted with 2,4,6-trimethylpyrylium tetrafluoroborate in the presence of HCl giving the (1-pyridino)imino complex  $[\text{W}^{\text{IV}}(\text{NNC}_5\text{H}_2\text{Me}_3)(\text{CO})(\text{PMe}_2\text{Ph})_2]^+$ .

Reaction of *cis*- $[\text{W}(\text{N}_2)_2(\text{dppe})_2]$  with triflic acid afforded *trans*- $[\text{W}^{\text{IV}}(\text{NNH}_2)(\text{dppe})_2(\text{OTf})]^+$ , which could also be

generated by reaction with two equivalents of *trans*- $[\text{Ru}(\eta^2\text{-H}_2)(\text{dppe})_2\text{Cl}][\text{OTf}]$  under hydrogen.

Treatment of  $[\text{WCl}_4(\text{PR}_3)_2]$  with two equivalents of  $\text{Me}_3\text{SiNHNMe}_2$  gave the bis(hydrazido(2-)) complex  $[\text{W}^{\text{VI}}(\text{NNMe}_2)_2(\text{PR}_3)_2\text{Cl}]^+$ . Reaction of  $[\text{W}(\text{NNPh}_2)\text{Cl}_4]$  with  $\text{Me}_3\text{SiCH}_2\text{MgCl}$  and  $\text{C}_6\text{F}_5\text{OH}$  in thf afforded  $[\text{W}(\text{NNPh}_2)(\text{CH}_2\text{SiMe}_3)_3(\text{OC}_6\text{F}_5)]$  whereas with  $\text{PhCH}_2\text{MgCl}$ ,  $[\text{W}(\text{NNPh}_2)\text{Cl}_2(\text{OC}_6\text{F}_5)_2(\text{thf})]$  was formed.

Reaction of  $[\text{W}(\text{NAr})\text{Cl}_4]$  (Ar = 2,6- $\text{Pr}^i_2\text{C}_6\text{H}_3$ ) with AgOTf followed by the tridentate pyridyl ligand L (45) afforded  $[\text{W}^{\text{VI}}(\text{NAr})\text{L}(\text{OTf})\text{Cl}]$ , which reacted with two equivalents of hydrazine giving the hydrazido(1-) complex  $[\text{W}(\text{NAr})(\kappa^2\text{-NNH}_2)\text{LCl}]$  (46).

(45)

(46)

Ligand exchange reactions involving  $[\text{W}(\text{NNPh}_2)(\text{O}^t\text{Bu})_4]$  with calixarenes afforded  $[\text{W}(\text{NNPh}_2)(\text{cal})]$ . The W–N–bond angle was nearly linear, and the W–N was short (1.74–1.75 Å) whereas the N–N distance was long (1.32–1.33 Å), consistent with a  $\text{W}=\text{N}-\text{NPh}_2$  bonding arrangement.

## 6.5 Tris(pyrazolyl)borato and Related Triaza Ligand Complexes

### 6.5.1 Nitrosyl Complexes

Treatment of  $[\text{W}(\text{NO})\text{Tp}^*\text{Cl}_2]$  [for  $\text{Tp}^*$  and related ligands see (47)] with 1,3:5,6-di-*O*-isopropylidene-D-glucufuranose,  $\text{HG}_f$ , afforded diastereoisomers of  $[\text{W}(\text{NO})\text{Tp}^*\text{Cl}(\text{OG}_f)]$ , a crystallographic study of the thermodynamically stable isomer establishing *S* absolute configuration at the metal atom.

(47)

$\text{Tp}^*$ , E = B, R' = H, R = Me

A series of complexes  $[\text{Fe}(\text{C}_5\text{H}_5)\{\text{C}_5\text{H}_4\text{QNHW}(\text{NO})\text{Tp}^*\text{Cl}\}]$ , where Q = nothing,  $\text{C}_6\text{H}_4$ ,  $\text{CH}=\text{CHC}_6\text{H}_4$ , or

$\text{N}=\text{NC}_6\text{H}_4$ , were prepared by reaction of the appropriate amino or anilino ferrocene with  $[\text{W}(\text{NO})\text{Tp}^*\text{Cl}_2]$ . Some of these complexes exhibited nonlinear optical properties, in particular, second order harmonic generation, although the response was significantly lower than that of their molybdenum counterparts.

### 6.5.2 Carbonyl Complexes

Treatment of  $[\text{W}(\text{CO})_3\text{Tp}^*]$  with bromine or iodine in acetonitrile afforded  $[\text{W}^{\text{II}}(\text{CO})_3\text{Tp}^*\text{X}]$  ( $\text{X} = \text{Br}, \text{I}$ ). Under certain circumstance, addition of  $\text{Br}_2$  also caused bromination of the  $\text{Tp}^*$  ligand at the 4-position on the pyrazole rings. These complexes were monodecarbonylated by heating in acetonitrile, the products being, for example,  $[\text{W}(\text{CO})_2\{\text{HB}(3,4\text{-Me}_2\text{-4-BrC}_3\text{N}_2)_3\}]$  and  $[\text{W}(\text{CO})(\eta^2\text{-NCMe})\{\text{HB}(3,4\text{-Me}_2\text{-4-BrC}_3\text{N}_2)_3\}]$ , the precise product being determined by the heating time. The structures of the sideways-bonded acetonitrile adduct ( $\text{C}-\text{N}$  1.10 Å) and that of the seven-coordinate  $[\text{W}(\text{CO})_3\{\text{HB}(3\text{-Pr}^i\text{C}_3\text{H}_2)_3\}\text{I}]$  were determined crystallographically.

The dinuclear species  $[\{\text{W}^{\text{II}}(\text{CO})_2\text{Tp}^*\}_2(\mu\text{-S})]$  was obtained by refluxing  $[\text{W}(\text{CO})_2\text{Tp}^*\text{Br}]$  or  $[\text{W}(\text{CO})_3\text{Tp}^*\text{H}]$  with propylene sulfide in 1,2-dichloroethane. The  $\text{W}-\text{S}-\text{W}$  chain is nearly linear, suggesting multiple bond character within the group, consistent with relatively short  $\text{W}-\text{S}$  bonds (2.17–2.18 Å).

Treatment of  $[\text{W}^{\text{II}}(\text{CO})_2\text{Tp}^*\text{I}]$ , obtained by prolonged refluxing of  $[\text{W}(\text{CO})_3\text{Tp}^*\text{I}]$  in thf, with alkyl and aryl thiolates afforded  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{SR})]$  ( $\text{R} = \text{Me}, \text{Et}, \text{Pr}^i, \text{CH}_2\text{Ph}$  or  $p\text{-C}_6\text{H}_4\text{NO}_2$ ). However, reaction of  $[\text{W}(\text{CO})_3\text{Tp}^*\text{Br}]$  with  $\text{NaSPr}^i$  in acetonitrile afforded  $[\{\text{W}(\text{CO})_2\text{Tp}^*\}_2\{\mu\text{-NC}(\text{Me})\text{C}(\text{Me})\text{N-}N,N'\}]$ , which contains a bridging *anti*-butane-2,3-diimino-(2-)-*N:N'* ligand formed by the coupling of two acetonitrile molecules.

Reaction of  $[\text{W}^{\text{II}}(\text{CO})(\eta^2\text{-NCMe})\text{Tp}^*\text{Br}]$  with  $(\text{S}_2\text{PR}'_2)^-$  ( $\text{R}' = (-)\text{-mentholate}$ ) afforded  $[\text{W}(\text{CO})(\eta^2\text{-NCMe})\text{Tp}^*(\kappa^1\text{-S}_2\text{PR}'_2)]$ , the structure of the (*R*)-isomer being determined crystallographically. Oxidative decarbonylation of  $[\text{W}(\text{CO})_3\text{Tp}^*]^-$  by tetraethylthiuramdisulfide,  $\text{Et}_2\text{NC}(\text{S})\text{SSC}(\text{S})\text{NEt}_2$ , afforded the seven-coordinate  $\text{W}^{\text{II}}$  species  $[\text{W}(\text{CO})_2\text{Tp}^*(\kappa^1\text{-S}_2\text{CNEt}_2)_2]$ , which had distorted pentagonal bipyramidal structure with a CO group and one N-donor atom of the  $\text{Tp}^*$  occupying the axial positions.

The seven-coordinate phosphine complexes  $[\text{W}^{\text{II}}(\text{CO})_3\text{Tp}^*\text{L}]^+$  were prepared by oxidation of the radical species  $[\text{W}(\text{CO})_3\text{Tp}^*]$  by ferrocenium cation, followed by addition of L ( $\text{PMe}_3$ ,  $\text{PET}_3$ ,  $\text{PPh}_3$ ,  $\text{PMe}_2\text{Ph}$ ). These species exhibited capped octahedral geometries.

Reaction of  $[\text{W}(\text{CO})_2\text{Tp}^*\text{I}]$  with ammonia in dichloromethane at low temperatures afforded the amido species  $[\text{W}^{\text{II}}(\text{CO})_2\text{Tp}^*(\text{NH}_2)]$  which, on treatment with LDA or  $\text{LiBu}^t$  followed by  $\text{MeI}$ , could be converted to  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NMe}_2)]$ . Hydride ion abstraction from  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NH}_2)]$  using  $\text{CPh}_3^+$  afforded the 'nitrene' species  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NR})]^+$

( $\text{R} = \text{H}, \text{CPh}_3$ ). Treatment of  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NH})]^+$  with base ( $\text{KH}$ , LDA, or  $\text{NEt}_3$ ) afforded the nitrido  $\text{W}^{\text{IV}}$  species  $[\text{W}(\text{CO})_2\text{Tp}^*(\equiv\text{N})]$  and reaction of this with  $\text{MeOTf}$  and  $\text{MeCOCl}$  afforded  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NMe})]^+$  and  $[\text{W}\text{Tp}^*\text{Cl}\{\text{NC}(\text{O})\text{Me}\}]$ , respectively. Heating  $[\text{W}(\text{CO})_3\text{Tp}^*\text{H}]$  with tosyl azide in thf gave the amido species  $[\text{W}^{\text{II}}(\text{CO})_2\text{Tp}^*(\text{NHtos})]$ .

Irradiation of  $[\text{W}(\text{CO})_3\text{Tp}^*\text{H}]$  in the presence of benzonitrile caused insertion of the nitrile into the  $\text{W}-\text{H}$  bond, giving  $[\text{W}^{\text{II}}(\text{CO})_2\text{Tp}^*(\text{N}=\text{CHPh})]$ , and related complexes  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NCHR})]$  ( $\text{R} = \text{Me}, \text{Et}$ ) were prepared similarly. Protonation of  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NCHR})]$  by  $\text{HBF}_4$  at low temperature afforded the cationic imido complexes  $[\text{W}^{\text{IV}}(\text{CO})_2\text{Tp}^*(=\text{NCH}_2\text{R})]^+$  ( $\text{R} = \text{Me}, \text{Et}, \text{CH}_2\text{Ph}$ ), but when  $\text{Ph}_3\text{CBF}_4$  was used instead of  $\text{HBF}_4$ ,  $[\text{W}^{\text{IV}}(\text{CO})_2\text{Tp}^*(=\text{NCH}(\text{R})\text{CPh}_3)]^+$  was formed.

Oxidative decarbonylation of  $[\text{W}(\text{CO})_3\text{Tp}^*]^-$  by tetraethylthiuram disulfide afforded a mixture of  $[\{\text{W}(\text{S}_2\text{CNEt}_2)_2\}_2(\mu\text{-S})]$  and  $[\text{W}^{\text{IV}}(\text{S})\text{Tp}^*(\text{S}_2\text{CNEt}_2)]$ .  $[\text{W}(\text{S})_2\text{Tp}^*(\text{OPh})]$  reacted with  $\text{MeO}_2\text{CC}\equiv\text{CCO}_2\text{Me}$  giving the dithiolato species  $[\text{W}^{\text{IV}}\text{Tp}^*(\text{OPh})\{\text{S}_2\text{C}_2(\text{CO}_2\text{Me})_2\}]$ .

Air oxidation of  $[\text{W}(\text{CO})_3\text{Tp}^*\text{I}]$  in refluxing toluene afforded  $\text{W}^{\text{IV}}(\text{O})(\text{CO})\text{Tp}^*\text{I}$ . Reaction of  $[\text{W}(\text{CO})\text{Tp}^*\text{I}(\kappa^2\text{-C},N\text{-NCMe})]$  with pyridine-*N*-oxide afforded the acylimino complex  $[\text{W}^{\text{IV}}(\text{CO})\text{Tp}^*(=\text{NC}(\text{O})\text{Me})\text{I}]$ , whereas reaction with propylene sulfide afforded  $[\text{W}^{\text{IV}}(\text{S})(\text{CO})\text{Tp}^*\text{I}]$ . Reaction of  $[\text{W}(\text{CO})\text{Tp}^*\text{I}\{\text{NC}(\text{O})\text{Me}\}]$  with  $\text{SPh}^-$  and with  $\{\text{S}_2\text{PPh}_2\}^-$  afforded  $[\text{W}^{\text{IV}}(\text{CO})\text{Tp}^*\{\text{NC}(\text{O})\text{Me}\}(\text{SPh})]$  and  $[\text{W}^{\text{IV}}(\text{CO})\text{Tp}^*\{\text{NC}(\text{O})\text{Me}\}(\kappa^1\text{-S}_2\text{PPh}_2)]$ . Propylene sulfide reacted with this last complex, affording the sulfido derivative  $[\text{W}^{\text{IV}}(\text{S})(\text{CO})\text{Tp}^*(\kappa^1\text{-S}_2\text{PPh}_2)]$ , and the analogous oxo species  $[\text{W}^{\text{IV}}(\text{O})(\text{CO})\text{Tp}^*(\kappa^1\text{-S}_2\text{PPh}_2)]$  was prepared by reaction of  $[\text{W}(\text{CO})_2\text{Tp}^*(\kappa^1\text{-S}_2\text{PPh}_2)]$ .

Treatment of the amido  $\text{W}^{\text{II}}$  complex  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NHtos})]$  ( $\text{tos} = \text{tosyl}$ ) with  $\text{AgOTf}$  or  $\text{I}_2$  afforded the 'nitrene' (or imido complex)  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{Ntos})]^+$ , and iodine or trityl cation oxidation of  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{NHR})]$  ( $\text{R} = \text{Bu}^t, \text{Ph}$ ) similarly afforded  $[\text{W}(\text{CO})_2(\text{NR})\text{Tp}^*]^+$ . The  $\text{W}-\text{N}-\text{C}$  bond angles and  $\text{W}-\text{N}$  distances were  $172^\circ$  ( $\text{R} = \text{Bu}^t$  and  $\text{Ph}$ ), and 1.72 Å ( $\text{R} = \text{Bu}^t$  and 1.76 Å ( $\text{R} = \text{Ph}$ ), respectively. A related carbene complex  $[\text{W}(\text{CO})_2\{\text{C}(\text{Ph})\text{Me}\}\text{Tp}^*]$  was also reported, in which there was an agostic interaction between a methyl hydrogen atom of the carbene and the metal. Reaction of  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{Ntos})]^+$  with  $\text{PMe}_3$  afforded the phosphinimine  $\text{Me}_3\text{P}=\text{Ntos}$ ,  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{PMe}_3)_2]^+$ , and  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{PMe}_3(\text{Ntos}))]^+$ .  $[\text{W}(\text{CO})_2\text{Tp}^*(\text{PMe}_3(\text{Ntos}))]\text{I}_3$  slowly decomposes to form  $[\text{W}(\text{CO})\text{Tp}^*(\text{Ntos})\text{I}]$ .

Reaction of  $\text{WCl}_6$  with  $\text{Me}_3\text{SiCH}=\text{CH}_2$  in ether and thf afforded  $[\text{WCl}_3(\text{thf})_2]$ , which reacted with  $\text{Tp}^*$  giving low yields of  $[\text{W}^{\text{V}}(\text{O})\text{Tp}^*\text{Cl}_2]$ . This complex reacted with mono and difunctional phenolates, affording  $[\text{W}^{\text{V}}(\text{O})\text{Tp}^*\text{Cl}(\text{OAr})]$  ( $\text{Ar} = \text{Ph}, 2,5\text{-Cl}_2\text{C}_6\text{H}_3, \text{C}_6\text{Cl}_5, \text{C}_6\text{H}_4\text{R-}p$  where  $\text{R} = \text{OMe}, \text{OH}, \text{C}_6\text{H}_4\text{OH}, \text{N}_2\text{C}_6\text{H}_4\text{OH}$ ) and the dinuclear  $[\{\text{W}^{\text{V}}(\text{O})\text{Tp}^*\text{Cl}\}_2(\text{OC}_6\text{H}_4\text{O})]$ ,  $[\{\text{W}^{\text{V}}(\text{O})\text{Tp}^*\text{Cl}\}_2(\text{OC}_6\text{H}_4\text{QC}_6\text{H}_4\text{O})]$ .

H<sub>4</sub>O)], and [W<sup>V</sup>(O)Tp\*Cl]<sub>2</sub>(OC<sub>6</sub>H<sub>4</sub>Cl<sub>2</sub>O)]. The tungsten atom in each of these species has pseudo-octahedral geometry. The mononuclear species could be electrochemically oxidized and reduced in reversible one-electron steps to W<sup>VI</sup> and W<sup>IV</sup> species, but none of these was isolated. The dinuclear complexes exhibited more complex redox behavior, oxidation occurring in discrete one-electron steps, generating mono and dications. Reduction occurred, at least for the species containing OC<sub>6</sub>H<sub>4</sub>O, in two clearly separate one-electron processes, but for the other species reduction appeared to occur in two nearly or actually coincident one-electron steps. From simple molecular orbital calculations, supported by detailed spectroelectrochemical and EPR spectral measurements, it was clear that for most of the complexes, the first one-electron oxidation resulted in the formation first of mixed-valence species (W<sup>V</sup>W<sup>VI</sup>) and the second process resulted in formation of the W<sup>VI</sup>W<sup>VI</sup> dication. Reduction resulted in generation of W<sup>IV</sup>W<sup>V</sup> and W<sup>IV</sup>W<sup>IV</sup> species, the interaction between the two oxidized species being significantly greater than that between the reduced species. The antiferromagnetic magnetic exchange interactions in the dinuclear species, apparent in the EPR spectra and quantified by the determination of *J* by solid-state susceptibility measurements, depended on the length and planarity of the bridging ligand and hence was strongest for [W(O)Tp\*Cl]<sub>2</sub>(OC<sub>6</sub>H<sub>4</sub>O)] and weakest for [W(O)Tp\*Cl]<sub>2</sub>OC<sub>6</sub>H<sub>4</sub>C<sub>6</sub>H<sub>4</sub>O]. The EPR spectra of the mono-oxidized dinuclear species indicated that these monocations were valence-trapped, at least on the EPR timescale. These dinuclear tungsten complexes exhibited weaker electronic and magnetic interactions than their molybdenum analogs probably because of poorer W–OAr *d*<sub>π</sub> – *p*<sub>π</sub> orbital overlap.

Oxidative hydrolysis of [W(CO)<sub>3</sub>TP\*]<sup>–</sup> afforded the mixed-valence species [Tp\*(O)<sub>2</sub>W(μ-O)W(CO)(O)Tp\*], which is believed to contain W<sup>VI</sup> and W<sup>IV</sup> centers.

### 6.5.3 Other Complexes

Reaction of [W(CO)<sub>3</sub>TP\*] with DMSO in the presence of water afforded [W<sup>VI</sup>TP\*(O)<sub>2</sub>(OH)], which, on treatment with OH<sup>–</sup>, afforded the octahedral species [WTP\*(O)<sub>3</sub>]<sup>–</sup>. Oxidation of [WTP\*(O)<sub>2</sub>(μ-O)W(CO)(O)TP\*] by Bu<sup>o</sup>OOH gave the dinuclear [{WTP\*(O)<sub>2</sub>]<sub>2</sub>(μ-O)].

Treatment of [W(CO)<sub>3</sub>TP\*]<sup>–</sup> with one equivalent of elemental sulfur in dmf afforded the mononuclear species [WTP\*(S)<sub>3</sub>]<sup>–</sup>, analogous to [WTP\*(O)<sub>3</sub>]<sup>–</sup>. A similar reaction using [W(CO)<sub>3</sub>TP]<sup>–</sup> afforded the trisulfide and [{WTP\*(O)(S)<sub>2</sub>]<sub>2</sub>(μ-S)]<sup>2–</sup>. Reaction of [WTP\*(O)<sub>2</sub>Cl] with B<sub>2</sub>S<sub>3</sub> or P<sub>4</sub>S<sub>10</sub> afforded [WTP\*(O)(S)Cl] and [WTP\*(S)<sub>2</sub>Cl], which reacted with OPh<sup>–</sup>, SPh<sup>–</sup>, SePh<sup>–</sup>, or (–)-mentholate (X) giving [WTP\*(O)(S)X] and [WTP\*(S)<sub>2</sub>X], the crystal structures of [W(S)<sub>2</sub>TP\*(OPh)] and (*R,S*)-[W(O)(S)TP\*(–)-mentholate] confirming their octahedral geometries.

Reaction of [WTP\*(S)<sub>2</sub>X] (X = monoanion) with alkynes afforded dithiolato complexes [W<sup>VI</sup>TP\*(S<sub>2</sub>C<sub>2</sub>R<sub>2</sub>)X] (R =

CO<sub>2</sub>Me or Ph; X = SePh or 2-quinoxaliny). Treatment of [W(CO)TP\*(S)(S<sub>2</sub>PR<sub>2</sub>)] (R = OEt or Ph) with pyridine-*N*-oxide in toluene afforded [W<sup>VI</sup>TP\*(O)(S)(κ<sup>1</sup>-S<sub>2</sub>PR<sub>2</sub>)], and when [WTP\*(O)(S)Cl] reacted with [Spy]<sup>–</sup> red [W<sup>VI</sup>TP\*(O)(S)(Spy)] was formed. In this last species, the pyridine thiolato ligand was monodentate and S-bonded. Reaction of [W<sup>VI</sup>TP\*(O)(S)(Spy)] with NO<sup>+</sup> afforded green paramagnetic [W<sup>V</sup>TP\*(O)(S<sub>2</sub>py)]<sup>+</sup> (**48**).

## 6.6 Complexes of Cyclic Triaza and Related Ligands

Photolysis of [W(CO)<sub>6</sub>] in the presence of Bu<sup>t</sup><sub>3</sub>tacn (**49**, R = Bu<sup>t</sup>), afforded [W(CO)<sub>3</sub>(Bu<sup>t</sup><sub>3</sub>tacn)], which has a piano-stool conformation similar to that of W(CO)<sub>3</sub>(Bu<sup>t</sup><sub>3</sub>tacn)]. Reaction of [W(CO)<sub>3</sub>(tdcn)] (tdcn = (**50**)) with NO<sup>+</sup> (prepared directly from NaNO<sub>2</sub>/HCl) gave [W(CO)<sub>2</sub>(NO)(tdcn)]<sup>+</sup>, which, on prolonged exposure to NO<sup>+</sup>, was converted to [W(NO)<sub>2</sub>(tdcn)Cl]<sup>+</sup>.

Oxidation of [W(CO)<sub>3</sub>(R<sub>3</sub>tacn)] (R = benzyl (**49**, R = CH<sub>2</sub>Ph) by ferrocenium cation afforded the air- and light-sensitive [W<sup>I</sup>(CO)<sub>3</sub>(R<sub>3</sub>tacn)]<sup>+</sup>. Oxidation of [W(CO)<sub>3</sub>(R<sub>3</sub>tacn)] (R = H (**49**, R = H), itself obtained by reaction of [W(CO)<sub>6</sub>] with R<sub>3</sub>tacn) by iodine afforded [W<sup>II</sup>(CO)<sub>3</sub>(R<sub>3</sub>tacn)I]<sup>+</sup>.

Oxidation of [W(CO)<sub>3</sub>(Bu<sup>t</sup><sub>3</sub>tacn)] [Bu<sup>t</sup><sub>3</sub>tacn = (**49**, R = Bu<sup>t</sup>)] by hydrogen peroxide afforded [W<sup>VI</sup>(Bu<sup>t</sup><sub>3</sub>tacn)(O)<sub>3</sub>], which also has octahedral symmetry.

## 6.7 Nitrosyl Complexes

Reaction of NO with [W(CO)<sub>2</sub>(phen)(SPh)<sub>2</sub>] gave [W(CO)<sub>2</sub>(NO)(phen)(SPh)], formally containing W<sup>0</sup>, together

with PhSNO. The NO group is trans to the thiophenolate ligand. Similar treatment of *cis*-W(CO)<sub>2</sub>(phen)(tdt) (tdt = toluene-3,4-dithiolate), the dinitrosyl *cis*-[W(NO)<sub>2</sub>(phen)(tdt)] was formed. [W(CO)<sub>3</sub>H(phen)(SPh)], the latter reacting with NO to give [W(CO)<sub>2</sub>(NO)(phen)(SPh)], N<sub>2</sub>O and HNO<sub>2</sub> (the last two by decomposition of eliminated HNO).

The hydrido complex *trans,trans*-[WH(CO)<sub>2</sub>(NO)(PR<sub>3</sub>)<sub>2</sub>] (R = Me, Et, Ph, OPr<sup>i</sup>) reacted with BH<sub>3</sub>·L (L = thf, SMe<sub>2</sub>) to give *trans*-[W(κ<sup>2</sup>-BH<sub>4</sub>)(CO)(NO)(PR<sub>3</sub>)<sub>2</sub>], which has octahedral geometry (R = Me confirmed crystallographically). [WH(CO)<sub>2</sub>(NO)(PMe<sub>3</sub>)<sub>2</sub>] reduced β-diketones to β-hydroxyketones with concomitant formation of *trans*-[W(diketonate)(CO)(NO)(PMe<sub>3</sub>)<sub>2</sub>].

Treatment of [W<sub>2</sub>H(CO)<sub>9</sub>(NO)] with tertiary phosphines or pyridine afforded mono and disubstituted complexes, two isomers existing for each compound, although only one was isolated successfully by column chromatography. The species [(OC)<sub>5</sub>W(μ-H)W(CO)<sub>3</sub>L(NO)] [L = P(*p*-C<sub>6</sub>H<sub>4</sub>F)<sub>3</sub>] and [(OC)<sub>5</sub>W(μ-H)W(CO)<sub>2</sub>L<sub>2</sub>(NO)] (L = py or P(*p*-C<sub>6</sub>H<sub>4</sub>F)<sub>3</sub>; L<sub>2</sub> = bipy) were characterized crystallographically. Treatment of [W<sub>2</sub>H(CO)<sub>7</sub>(thf)<sub>2</sub>(NO)] with the sterically bulky PBu<sub>3</sub> caused monosubstitution, giving [W<sub>2</sub>H(CO)<sub>8</sub>(PBu<sub>3</sub>)(NO)], and also abstraction of the hydride with formation of [HPBu<sub>3</sub>]<sup>+</sup> as well as [W<sub>2</sub>(μ-H)(CO)<sub>10</sub>]<sup>-</sup> and [W<sub>3</sub>(μ-H)<sub>2</sub>(CO)<sub>13</sub>(NO)]<sup>-</sup>. The trinuclear tungsten nitrosyl dihydride was also formed by reaction of [W<sub>2</sub>H(CO)<sub>9</sub>(NO)] with [W(CO)<sub>5</sub>H]<sup>-</sup>, and reacted with PMe<sub>3</sub> giving [W<sub>3</sub>(μ-H)<sub>2</sub>(CO)<sub>12</sub>(PMe<sub>3</sub>)(NO)]<sup>-</sup> (51).

[W(NO)(SBU<sup>t</sup>)<sub>3</sub>(py)] was prepared by reaction of [W(NO)(OBU<sup>t</sup>)<sub>3</sub>(py)] with an excess of Bu<sup>t</sup>SH in toluene. The structure of this molecule was trigonal bipyramidal, in which the py and NO ligands were in axial positions. The W–N–O bond was linear.

## 7 COMPLEXES WITH P-, As-, Sb-, AND Bi-DONOR ATOMS

When *trans*-[W(N<sub>2</sub>)<sub>2</sub>(dppe)<sub>2</sub>] was irradiated in the presence of 1,4-diisocyanobenzene and 4-isocyanobenzonitrile, *cis*-[W(CNC<sub>6</sub>H<sub>4</sub>NC)<sub>2</sub>(dppe)<sub>2</sub>] and *cis*-[W(CNC<sub>6</sub>H<sub>4</sub>CN)<sub>2</sub>(dppe)<sub>2</sub>] were formed. The isocyanide ligands exhibited bent W–C–NAr bonds.

Reduction of WCl<sub>6</sub> by an excess of Mg powder in the presence of 4,4',5,5'-tetramethyl-2,2'-diphosphinine, tmbp (52) (E = P), a fully phosphinated analog of 2,2'-dipyridyl, afforded the trigonal [W(tmbp)<sub>3</sub>]. A regular octahedral complex would have a twist angle θ = 60° and in this complex the twist angle θ is 15 ± 0.6° indicating that the ligand may be partially reduced, a situation reminiscent of the behavior of tris(dithiolene) complexes. UV irradiation of [W(CO)<sub>6</sub>] with (52) (E = N), another analog of 2,2'-dipyridyl, afforded [W(CO)<sub>4</sub>(κ<sup>2</sup>-C<sub>12</sub>H<sub>12</sub>NP-N, P)].

Reaction of [W(CO)<sub>5</sub>(thf)] with the phosphorus-antimony cage P<sub>4</sub>Sb<sub>2</sub>C<sub>4</sub>Bu<sup>t</sup><sub>4</sub> afforded the dinuclear [{W(CO)<sub>5</sub>}(κ<sup>1</sup>-P<sub>4</sub>Sb<sub>2</sub>C<sub>4</sub>Bu<sup>t</sup><sub>4</sub>-P, Sb)] (53).

Reaction of [W(CO)<sub>5</sub>Br]<sup>-</sup> and *fac*-W(CO)<sub>3</sub>(NCMe)<sub>3</sub> with Me<sub>2</sub>SbCH<sub>2</sub>SbMe<sub>2</sub> afforded [W(CO)<sub>5</sub>(κ<sup>1</sup>-Me<sub>2</sub>SbCH<sub>2</sub>SbMe<sub>2</sub>)] and *fac*-[W(CO)<sub>3</sub>(κ<sup>1</sup>-Me<sub>2</sub>SbCH<sub>2</sub>SbMe<sub>2</sub>)<sub>3</sub>] whereas W(CO)<sub>5</sub>(thf), [W(CO)<sub>6</sub>], and [W(CO)<sub>4</sub>(Me<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>NMe<sub>2</sub>)] reacted with Ph<sub>2</sub>SbCH<sub>2</sub>SbPh<sub>2</sub> affording [(OC)<sub>5</sub>W(μ-Ph<sub>2</sub>SbCH<sub>2</sub>SbPh<sub>2</sub>)W(CO)<sub>5</sub>] and *cis*-[W(CO)<sub>4</sub>(κ<sup>1</sup>-Ph<sub>2</sub>SbCH<sub>2</sub>SbPh<sub>2</sub>)<sub>2</sub>], respectively.

Treatment of the cyclic [As(PBu<sup>t</sup>)<sub>3</sub>]<sup>-</sup> with water afforded [Bu<sup>t</sup>P(PHBu<sup>t</sup>)<sub>2</sub>], which subsequently reacted with [W(CO)<sub>5</sub>(thf)] giving [W(CO)<sub>4</sub>(κ<sup>2</sup>-(Bu<sup>t</sup>P)<sub>2</sub>PBu<sup>t</sup>-P, P')]. Reaction of [W<sub>2</sub>(CO)<sub>10</sub>]<sup>2-</sup> with PCl<sub>3</sub> afforded a mixture of [W(CO)<sub>5</sub>(PCl<sub>3</sub>)], [{W(CO)<sub>5</sub>}(μ-PCl)], and [W(CO)<sub>5</sub>{μ, η<sup>2</sup>:κ<sup>1</sup>:κ<sup>1</sup>-P<sub>2</sub>Cl<sub>2</sub>[W(CO)<sub>5</sub>]}].

The phosphole complex (**54**) reacted with  $\text{MeO}_2\text{CC}\equiv\text{CCO}_2\text{Me}$  giving phosphanornadiene complexes (**55**). This reacted in turn with  $\text{PEt}_3$  giving a phosphoranylidenephosphine complex  $[\text{W}(\text{CO})_5\{\text{EtO}_2\text{CPPEt}_3\}]$ , in which the P–P bond length (2.16 Å) was closer to a single bond than to a double bond, consistent with zwitterionic character in the diphosphorus ligand, viz.  $\{\text{EtO}_2\text{CP}^--^+\text{PEt}_3\}$ . A similar zwitterionic situation appears to have occurred in the diphosphate derivative (**56**) ( $\text{R} = \text{SiMe}_3$ ), which reacted with  $\text{F}^-$  affording (**56**) ( $\text{R} = \text{H}$ ).

Reaction of  $\text{trans-W}(\text{N}_2)_2(\text{dppe})_2$  with aromatic isocyanides afforded *cis*- and *trans*- $[\text{W}(\text{CNAr})_2(\text{dppe})_2]$  ( $\text{Ar} = p\text{-RC}_6\text{H}_4$  where  $\text{R} = \text{CF}_3, \text{NO}_2, \text{CN}, \text{NC}, \text{F},$  and  $\text{Me}$ ).

Treatment of  $[\text{W}(\text{CO})_3(\eta^6\text{-C}_6\text{H}_3\text{Me}_3)]$  with  $\text{K}_3\text{P}_7$  (**57**) and 2,2,2-crypt in 1,2-diaminoethane afforded  $[\text{W}(\text{CO})_3(\text{P}_7)]^{3-}$  (**58**), which could be alkylated and protonated giving  $[\text{W}(\text{CO})_3(\text{P}_7\text{Et})]^{2-}$  (**59**) and  $[\text{W}(\text{CO})_4(\text{P}_7\text{H})]^{2-}$  (**60**). Under CO at atmospheric pressure, (**58**) was converted to  $[\text{W}(\text{CO})_4(\kappa^2\text{-P}_7)]^{3-}$ .

Reaction of  $[\text{W}(\text{CO})_5]^{2-}$  with  $(\text{Me}_3\text{Si})_2\text{CHBiCl}_2$  afforded  $[\{\text{W}(\text{CO})_5\}_2(\mu_3\text{-}\kappa^2\text{-Bi}_2)]$  (**61**) and  $[\text{W}_2(\text{CO})_8(\mu\text{-}\kappa^2\text{-Bi}_2)(\mu\text{-BiMe})\text{W}(\text{CO})_5]$  (**62**). The species (**62**) contains a  $\text{Bi}_2$  group bridging two W atoms and if the Bi–Bi bond order is regarded as one, then the formal oxidation state of the transition metal is II. However, the Bi–Bi bond is quite short (2.80 Å) and

corresponds approximately to a bond order of 2, and so the formal oxidation state of the tungsten atoms is between I and II.

Reaction of  $[\text{W}(\text{CO})_5]^{2-}$  with  $\text{Br}_2\text{BN}(\text{SiMe}_3)_2$  afforded the terminal borylene complex  $[\{(\text{Me}_3\text{Si})_2\text{NB}=\text{W}(\text{CO})_5\}]$ , which is octahedral, with a linear W–B–N group and short B–N bonds (1.34 Å).

Reaction of  $[\text{WCl}_2(\text{PMe}_3)_4]$  with  $\text{ArP}=\text{C}=\text{O}$  ( $\text{Ar} = 2,4,6\text{-Bu}'_3\text{C}_6\text{H}_2$ ) afforded the  $\text{W}^{\text{IV}}$  complex  $[\text{W}(=\text{PAr})(\text{CO})(\text{PMe}_3)\text{Cl}_2]$ , in which the W–P–C group was essentially linear ( $168^\circ$ ).

Treatment of  $[\text{WCl}(\text{Me}_3\text{SiNCH}_2\text{CH}_2)_3\text{N}]$  with  $\text{LiPHPh}$  afforded the phosphido tungsten (VI) species  $[\text{W}(=\text{P})(\text{Me}_3\text{SiNCH}_2\text{CH}_2)_3\text{N}]$  (**63**,  $\text{R} = \text{SiMe}_3$ ), and the corresponding arsenido complex,  $[\text{W}(=\text{As})(\text{Me}_3\text{SiNCH}_2\text{CH}_2)_3\text{N}]$  (very low yield), together with  $[\text{WPh}\{(\text{Me}_3\text{SiNCH}_2\text{CH}_2)_3\text{N}\}]$ , was obtained using  $\text{LiAsHPh}$ . The arsenide was obtained in more substantial yields in the reaction between  $[\text{WPh}\{(\text{Me}_3\text{SiNCH}_2\text{CH}_2)_3\text{N}\}]$  and a small excess of  $\text{AsH}_2\text{Ph}$ .

## 8 HYDRIDO AND BOROHYDRIDO COMPLEXES

Photolysis of  $[\text{W}(\text{CO})_6]$  in the presence of  $\text{B}_2\text{H}_4(\text{PMe}_3)_2$  afforded  $[\text{W}(\text{CO})_5\{\kappa^1\text{-HB}_2\text{H}_3(\text{PMe}_3)_2\}]$  (**64**) and  $[\text{W}(\text{CO})_4$

$\{(\kappa^2\text{-H}_2\text{B}_2\text{H}_2(\text{PMe}_3)_2)\}$  (65). Analogous reactions involving  $\text{BH}_3(\text{PR}_3)$  ( $\text{R} = \text{Me}, \text{Ph}$ ) or  $\text{BH}_3(\text{NMe}_3)$  afforded  $[\text{W}(\text{CO})_5(\kappa^1\text{-HBH}_2\text{L})]$  ( $\text{L} = \text{PR}_3$  or  $\text{NMe}_3$ ) (66).

The species previously formulated as  $[\text{W}(\text{PMe}_3)_4\text{H}_2(\text{H}_2\text{O})\text{F}]\text{F}$  was reformulated as  $[\text{W}^{\text{IV}}(\text{PMe}_3)_4\text{H}_2\text{F}_2(\text{H}_2\text{O})]$  or  $[\text{W}(\text{PMe}_3)_4\text{H}_2\text{F}_2(\text{FHF})]$ . Treatment of  $[\text{W}(\text{PMe}_3)_4(\kappa^2\text{-CH}_2\text{PMe}_2)\text{H}]$  with aqueous  $\text{HCl}$  afforded  $[\text{W}^{\text{IV}}(\text{PMe}_3)_4\text{H}_2\text{Cl}_2]$  and anion exchange with bromide and iodide gave  $[\text{W}(\text{PMe}_3)_4\text{H}_2\text{X}_2]$  ( $\text{X} = \text{Br}$  or  $\text{I}$ ). The structure of these species is represented as (67) ( $\text{X} = \text{Y} = \text{F}, \text{Cl}, \text{Br}, \text{I}$ ;  $\text{X} = \text{F}, \text{Y} = \text{F} \cdots \text{H-F}$ ).

Controlled potential electrolysis of  $[\text{WH}_2(\kappa^2\text{-O}_2\text{CMe})(\text{dppe})_2]^+$  containing one equivalent of  $\text{MeCO}_2\text{H}$  afforded  $[\text{W}^{\text{IV}}\text{H}_3(\kappa^1\text{-OCOMe})(\text{dppe})_2]$  in high yields.

## 9 METAL–METAL BONDED COMPLEXES AND CLUSTER COMPOUNDS

### 9.1 Dinuclear Complexes

Several reviews of ditungsten compounds having multiple bonds have described this area.<sup>4,8</sup> In very general terms, the

formal bond order for ditungsten compounds ranges from four to less than unity. The range of bond lengths varies from ca. 2.30 Å, formally representing a quadruple bond, to ca. 2.83 Å, formally representing a single bond, although variations occur depending on the nature of the terminal and bridging ligands. Quadruply bonded species are normally encountered in  $\text{W}^{\text{II}}\text{W}^{\text{II}}$  complexes, triply bonded species in  $\text{W}^{\text{III}}\text{W}^{\text{III}}$  compounds, and doubly bonded species in  $\text{W}^{\text{IV}}\text{W}^{\text{IV}}$  complexes. Dinuclear complexes containing the  $\text{W}^{\text{V}}\text{W}^{\text{V}}$  core usually have W–W single bonds. A significant number of multiply bonded ditungsten complexes carry the  $\eta^5\text{-C}_5\text{H}_5$  or related ligands but these are not discussed here.

Probably the most dominant species amongst the dinuclear species are those containing  $\text{W}^{\text{III}}$ , lower oxidation state species being highly susceptible to oxidation.

#### 9.1.1 Complexes Containing $\text{W}^{\text{II}}\text{W}^{\text{II}}$

The dominant structural feature of complexes containing  $\text{W}_2^{4+}$  is the presence of a quadruple bond. However, the ditungsten core is extremely sensitive to oxidative addition and consequently the chemistry of  $\text{W}^{\text{II}}\text{W}^{\text{II}}$  species is less well developed than that of molybdenum. However,  $[(\text{Me}_3\text{P})_2(\text{MeCC})_2\text{WWCl}_2(\text{PMe}_3)_2]$  ( $d_{\text{W-W}} 2.27 \text{ Å}$ ) was obtained by reaction of  $[\text{W}_2\text{Cl}_4(\text{PMe}_3)_4]$  with  $\text{LiC}\equiv\text{CMe}$ . A range of complexes containing carboxylates, amines, N-based chelating ligands, tertiary phosphines, and halides has also been described. Addition of  $\text{PhICl}_2$  to  $[\text{W}_2\text{Cl}_4(\text{PMe}_3)_4]$  afforded the mixed-valent  $\text{W}^{\text{III}}\text{W}^{\text{II}}$  species  $[\text{W}_2\text{Cl}_5(\text{PMe}_3)_3]$  ( $d_{\text{W-W}} 2.43 \text{ Å}$ ).

#### 9.1.2 Complexes Containing $\text{W}^{\text{III}}\text{W}^{\text{III}}$

The simplest dinuclear tungsten (III) species are of the type  $[\text{W}_2\text{X}_6]$  have an ethane-like structure and have W–W bonds in the range 2.26–2.29 Å. A smaller but significant group also contain the  $\{\text{W}_2\text{X}_6\}$  core but carry two or three additional neutral ligands and in some species, although the ditungsten core can be defined as carrying a +6 charge, the two W atoms may have different formal oxidation states. In general, in these latter species, the W–W bond distances are slightly larger than in  $[\text{W}_2\text{X}_6]$ , within the range 2.31–2.50 Å, depending on the coligands.

Reduction of  $\text{WCl}_4$  by one equivalent of  $\text{NaBHET}_3$  in the presence of  $\text{Lihpp}$  ( $\text{hppH} = (68)$ ) afforded  $[\text{W}_2(\text{hpp})_4\text{Cl}_2]$  ( $\text{W-W} 2.25 \text{ Å}$ ).

However, reduction of  $\text{WCl}_4$  using sodium amalgam in the presence of an excess of tertiary phosphine  $\text{L}$  afforded  $[\text{W}_2(\mu\text{-Cl})_2\text{Cl}_4\text{L}_4]$  [ $\text{L} = \text{PMe}_2\text{Ph}$  ( $d_{\text{W-W}}$  2.70 Å);  $\text{L} = \text{PEt}_3$  ( $d_{\text{W-W}}$  2.74 Å),  $\text{PMe}_3$  ( $d_{\text{W-W}}$  2.71 Å)]. These complexes have edge-sharing dioctahedral geometries, but their face-sharing analogs  $[\text{W}_2(\mu\text{-X})_3\text{X}_3\text{L}_3]$  were obtained by restricting the amount of  $\text{L}$  used in the reaction. Species characterized crystallographically included  $[\text{W}_2(\mu\text{-Cl})_3\text{Cl}_3(\text{PMe}_2\text{Ph})_3]$  ( $d_{\text{W-W}}$  2.44 Å),  $[\text{W}_2(\mu\text{-Cl})_3\text{Cl}_3(\text{PEt}_3)_3]$  ( $d_{\text{W-W}}$  2.47 Å), and  $[\text{W}_2(\mu\text{-Br})_3\text{Br}_3(\text{PMe}_2\text{Ph})_3]$  (obtained from  $\text{WBr}_5$ ) ( $d_{\text{W-W}}$  2.48 Å). Addition of water to  $[\text{W}_2(\mu\text{-Cl})_3\text{Cl}_3(\text{PEt}_3)_3]$  afforded  $[\text{W}_2(\mu\text{-Cl})_3\text{Cl}_4(\text{PEt}_3)_3]^-$  ( $d_{\text{W-W}}$  2.44 Å).

When  $\text{WCl}_4$  was reduced by sodium amalgam in the presence of thioethers such as  $\text{SEt}_2$ , 1,4-dithiane, 1,4-dithioxane, or pentamethylene sulfide, the sulfur rather than Cl ligand frequently acted as the bridging ligand, viz.  $[\text{W}_2(\mu\text{-SR}_2)_3\text{Cl}_6]$  (**69**) ( $\text{L} = \text{SEt}_2$ ,  $d_{\text{W-W}}$  2.50 Å,  $\text{L} = 1,4$ -dithiane,  $d_{\text{W-W}}$  2.48 Å,  $\text{L} = 1,4$ -dithioxane,  $d_{\text{W-W}}$  2.50 Å,  $\text{L} =$  pentamethylene sulfide,  $d_{\text{W-W}}$  2.51 Å). However, reaction with  $\text{SMe}_2$  invariably afforded  $[\text{W}_2(\mu\text{-Cl})(\mu\text{-SMe}_2)_2\text{Cl}_6]^-$  and the precise nature of these bridged species (i.e. exclusively bridging  $\text{SR}_2$  or mixtures of halide and  $\text{SR}_2$ ) was dependent on reaction conditions. The bridging sulfur centers in the anionic species were susceptible to attack by anions  $\text{X}^-$  ( $\text{X} = \text{SR}$ ,  $\text{SeR}$ ,  $\text{Cl}$ ,  $\text{Br}$  or  $\text{H}$ ), resulting in loss of an alkyl group, as in conversion of  $[\text{W}_2(\mu\text{-SEt}_2)_3\text{Cl}_6]$  to  $[\text{W}_2(\mu\text{-Cl})(\mu\text{-SEt})(\mu\text{-SEt}_2)\text{Cl}_6]^-$  ( $d_{\text{W-W}}$  2.44 Å) by treatment of the former with  $[\text{SC}_6\text{H}_4\text{Me}]^-$ . Further, cyclic species, such as those containing  $\mu$ -tetrahydrothiophene, underwent ring opening on addition of  $\text{Cl}^-$  giving  $[\text{W}_2(\mu\text{-SC}_4\text{H}_8)_2(\mu\text{-SCH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl})\text{Cl}_6]^-$  ( $d_{\text{W-W}}$  2.49 Å).

### 9.1.3 Complexes Containing $\text{W}^{\text{IV}}\text{W}^{\text{IV}}$

Reaction of  $[\text{W}_2(\text{OR})_6(\text{py})_2]$  ( $\text{R} = \text{CH}_2\text{Bu}'$ ) with 1,3-butadiene and with isoprene afforded blue-black  $[\text{W}_2(\mu\text{-}\kappa^1\text{-}\eta^4\text{-C}_4\text{H}_6)(\mu\text{-OR})_2(\text{OR})_4(\text{py})]$  (**70**) ( $d_{\text{W-W}}$  2.49 Å) and  $[\text{W}(\mu\text{-}\kappa^1\text{-}\eta^4\text{-C}_5\text{H}_8)(\mu\text{-OR})_2(\text{OR})_4(\text{py})]$  ( $d_{\text{W-W}}$  2.46 Å). The metal-metal separations were indicative of double bonds.

In the reaction between  $[\text{W}_2(\text{OR}'')_6]$  ( $\text{R}'' = \text{SiMe}_2\text{Bu}'$ ) and  $\text{NO}$  in hydrocarbon solvents containing pyridine,  $[\text{W}(\text{NO})(\text{OR}'')_3(\text{py})_2]$ ,  $[\text{WO}(\text{OR}'')_4(\text{py})]$ , and  $[\text{W}_2\text{O}_4(\text{OR}'')_4(\text{py})_2]$  were formed. An intermediate  $[\text{W}_2(\mu\text{-O})(\mu\text{-OR}'')$

$(\text{OR}'')_5(\text{py})_2]$  was apparently formed along with  $\text{N}_2\text{O}$  after the coupling of two nitrosyl ligands during this reaction. This subsequently decomposed with loss of  $\text{W-W}$  bonding and the generation of the tungsten oxo complexes, which were also thought to arise from reactions involving  $\text{N}_2\text{O}$ . Both  $[\text{W}^{\text{VI}}\text{O}_4(\text{OR}'')_4(\text{py})_2]$  ( $d_{\text{W-W}}$  3.04 Å) and  $[\text{W}_2(\mu\text{-O})(\mu\text{-OR}'')(\text{OR}'')_6(\text{py})_2]$  ( $d_{\text{W-W}}$  2.49 Å) were characterized crystallographically.

The species  $[\text{W}_2(\text{OBU}')_7]^-$ , which existed in an equilibrium with  $[\text{W}_2(\text{OBU}')_6]$  and  $[\text{OBU}']^-$ , decomposed forming red  $[\text{W}_2(\mu\text{-O})(\mu\text{-H})(\text{OR})_6]^-$  with concurrent loss of  $\text{Me}_2\text{C}=\text{CH}_2$ . The structure of the oxo-hydride was confirmed crystallographically, the metal-metal distance ( $d_{\text{W-W}}$  2.44 Å), being consistent with a double bond in a  $\text{W}_2^{8+}$  core.  $[\text{W}_2(\text{OR}')_6(\text{NHMe}_2)_2]$  ( $\text{R} = \text{cyclo-C}_5\text{H}_9$ ) also decomposed over four days in the presence of cyclopentanol, affording a bridging hydride species  $[\text{W}_2(\mu\text{-H})(\mu\text{-OR}')(\text{OR}')_5(\text{NHMe}_2)]$  ( $d_{\text{W-W}}$  2.44 Å). This molecule was fluxional in solution, and the dimethylamine could be replaced by  $\text{PMe}_3$ .

Treatment of  $[\text{W}_2\text{Cl}_2(\text{NMe}_2)_4]$  with  $\text{Li}_2\text{C}_8\text{H}_8$  afforded  $[\text{W}^{\text{IV}}_2(\mu\text{-}\eta^5, \eta^5\text{-C}_8\text{H}_8)(\text{NMe}_2)_4]$  (**71**) ( $d_{\text{W-W}}$  2.43 Å), in which the hydrocarbon ligand, regarded formally as  $\text{C}_8\text{H}_8^{4-}$ , functioned as a four electron bridging group.

### 9.1.4 Complexes Containing $\text{W}^{\text{V}}\text{W}^{\text{V}}$

Treatment of  $\text{cis-}[\text{WF}_2(\text{OMe})_4]$  in  $\text{thf}$  with lithium powder, followed by an excess of  $\text{NaOMe}$ , afforded  $[\text{W}_2(\text{OMe})_{10}]$ , which has an edge-sharing dioctahedral structure ( $d_{\text{W-W}}$  2.79 Å). Aldehydes  $\text{RCHO}$  ( $\text{R} = \text{cyclopropyl}$ ,  $\text{tolyl}$ ,  $\text{anisyl}$ ) reacted with  $[\text{W}^{\text{III}}_2(\text{ONp})_6(\text{py})_2]$  ( $\text{Np} = \text{CH}_2\text{Bu}'$ ) giving alkylidene complexes  $[\text{W}_2(\mu\text{-ONp})_2(\text{ONp})_4(\mu\text{-CHR})(\text{O})(\text{py})]$  (**72**) ( $\text{R} = \text{cyclopropyl}$  or  $\text{tolyl}$ ,  $d_{\text{W-W}}$  2.66 Å). These complexes reacted with an excess of pyridine giving  $[\text{W}_2(\mu\text{-CR})(\mu\text{-O})(\text{ONp})_5(\text{py})_2]$ , (**73**) ( $\text{R} = \text{cyclopropyl}$  or  $\text{anisyl}$ ,  $d_{\text{W-W}}$  2.45 Å). Reaction of  $[\text{W}^{\text{III}}_2(\text{OR})_6(\text{py})_2]$  with cyclohexenone afforded  $[\text{W}_2(\mu\text{-O})(\mu\text{-OC}_{12}\text{H}_{16})(\text{OR})_6]$  ( $d_{\text{W-W}}$  2.82 Å) and other dinuclear species containing  $\text{W}^{\text{V}}$  centers were obtained from reaction with acrolein ( $d_{\text{W-W}}$  2.65 Å), methyl vinyl ketone ( $d_{\text{W-W}}$  2.79 Å), and crotonaldehyde ( $d_{\text{W-W}}$  2.62 Å).

Reaction of cooled solutions of  $[\text{W}^{\text{IV}}_2(\mu\text{-H})(\mu\text{-OR}')_2(\text{OR}')_5(\text{NHMe}_2)]$  ( $\text{R}' = \text{cyclo-C}_5\text{H}_9$ ) with four equivalents of ethane afforded the diamagnetic  $[\text{W}_2(\mu\text{-OR}')_3(\text{OR}')_4\text{Et}(\eta^2\text{-C}_2\text{H}_4)]$  (**74**) ( $d_{\text{W-W}}$  2.67 Å).  $[\text{W}_4(\mu\text{-H})_2(\mu\text{-OPr})_6(\text{OPr})_8]$  reacted similarly but no crystalline product was obtained.

When two equivalents of cyclopentanone in hexane were added to the same hydrido precursor, diamagnetic  $[\text{W}_2(\mu\text{-OR}')_3(\text{OR}')_5(\eta^2\text{-OC}_5\text{H}_8)]$  (**75**) ( $d_{\text{W-W}}$  2.67 Å) was formed. Treatment of  $[\text{W}_4\text{H}_2(\text{OPr}')_{14}]$  with benzophenone in pentane afforded the analogous  $[\text{W}_2(\text{H})(\mu\text{-OPr}')_3(\text{OPr}')_4(\eta^2\text{-OCPh}_2)]$  ( $d_{\text{W-W}}$  2.65 Å), in which one terminal alkoxido group was replaced by hydride. Reaction of the tetranuclear dihydride with nitriles led to coupling of the nitrile molecules and formation of a dinuclear species  $[\text{W}_2(\mu\text{-OPr}')_2(\text{OPr}')_5\{\text{NC}(\text{Ph})\text{C}(\text{Ph})\text{NH}\}]$  (**76**) ( $\text{R}' = \text{Ph}$ ,  $d_{\text{W-W}}$  2.59 Å).

Addition of *t*-butanol to hydrocarbon solutions of  $[\text{W}_2(\kappa^1\text{-SC}_4\text{H}_3)_2(\text{NMe}_2)_4]$  afforded  $[\text{W}_2(\mu\text{-SC}_4\text{H}_4(\kappa^1\text{-SC}_4\text{H}_3)(\text{OBu}^t)_5)]$  ( $d_{\text{W-W}}$  2.63 Å). Treatment of  $[\text{W}_2(\text{OR})_8]$  ( $\text{R} = \text{CH}_2\text{Bu}^t$ ) with pyridine-*N*-oxide and elemental sulfur, elemental selenium, and tellurium afforded  $[\text{W}_2(\mu\text{-E})(\mu\text{-OR})_2(\text{OR})_6]$  (**77**) ( $\text{E} = \text{O}, \text{Se}$  or  $\text{Te}$ ), in which the metal–metal bond was in the range 2.55–2.66 Å.

Treatment of  $[\text{W}_2\text{S}_4\text{Br}_4]^{2-}$  with  $\text{PPh}_3$  afforded  $[\text{W}_2(\mu\text{-S})_2\text{S}_2\text{Br}_2(\text{PPh}_3)_2]$ , which contains the *syn*-(S)W( $\mu$ -) $\text{S}(\text{S})^{2+}$  fragment ( $d_{\text{W-W}}$  2.81 Å). When  $[\text{WSe}_4]^{2-}$  was stirred in an MeCN/ $\text{CH}_2\text{Cl}_2$  solution with  $\text{PPh}_3$ ,  $[\text{W}_2\text{Se}_6]^{2-}$  ( $d_{\text{W-W}}$  2.85 Å) was formed. Further reaction of this species with  $\text{P}(c\text{-C}_6\text{H}_{11})_3$  in the presence of copper (I) chloride afforded the cluster species  $[\text{Cu}\{\text{P}(c\text{-C}_6\text{H}_{11})_3\}_2(\mu\text{-Se}_2\text{WSe}_2)\text{Cu}\{\text{P}(c\text{-C}_6\text{H}_{11})_3\}_2]$  and the cubane-like  $[\text{W}_2(\mu_3\text{-Se})_4(\kappa^2\text{-Se}_2\text{CH}_2)_2\text{Cu}\{\text{P}(c\text{-C}_6\text{H}_{11})_3\}_2]$ .

The diamagnetic  $[\text{W}_2(\mu\text{-CNEt}_2)(\mu\text{-S})(\mu\text{-S}_2\text{CNEt}_2)(\mu\text{-S}_2\text{SnCHSiMe}_3)(\text{S}_2\text{CNEt}_2)_2]$  ( $d_{\text{W-W}}$  2.61 Å) was formed by refluxing the mononuclear  $[\text{W}(\text{CO})_2(\text{S}_2\text{CNEt}_2)(\text{SnCHSiMe}_3)]$  in benzene. Addition of *N*-bromophthalimide to a chloroform solution of  $[\{\text{W}_2(\text{Ntol})\{\text{S}_2\text{P}(\text{OEt})_2\}\text{S}\}_4]$  containing  $[\text{Et}_4\text{N}][\text{OAc}]$  afforded the sulfur-bridged species  $[\text{W}_2(\text{Ntol})_2\{\text{S}_2\text{P}(\text{OEt})_2\}_2(\mu\text{-OAc})(\mu\text{-S})(\mu\text{-SBr})]$  (**78**) ( $d_{\text{W-W}}$  2.83 Å).

Pyridine reacted at 60 °C with  $[\text{W}_2\text{Cl}_2(\text{NHSiBu}^t_3)_4]$  to give  $[\text{WHCl}(\text{NSiBu}^t_3)_2(\text{py})]$ ,  $[\text{WCl}_2(\text{NBu}^t_3)_2(\text{py})]$ , and  $[\text{W}_2(\mu\text{-H})_2(\mu\text{-Cl})\text{HCl}_2(\text{NHSiBu}^t_3)_3(\text{py})_2]$  (**79**) ( $d_{\text{W-W}}$  2.79 Å).

## 9.2 Polyoxoanions

Polyoxometallate ions containing tungsten form an enormous range of compounds, which have been reviewed extensively.<sup>5,6</sup> They may be subdivided into (1) isopolyanions containing W as the dominant and frequently the only metal component, and (2) heteropolyanions where other metals and/or nonmetal atoms may be present in the core structure.

### 9.2.1 Isopolyanions

NMR studies have demonstrated that above pH 6 the major polytungstate species are  $[\text{W}_7\text{O}_{24}]^{6-}$  (known

also as paratungstate-A) and  $[\text{H}_2\text{W}_{12}\text{O}_{42}]^{10-}$  (known as paratungstate-B). These species have been isolated as several different types of salt, and have been characterized crystallographically and by their  $^{183}\text{W}$  chemical shifts. Below pH 5.5, equilibria are slowly established and most polytungstate species, excepting the Keggin ion  $\alpha\text{-}[(\text{H}_2)\text{W}_{12}\text{O}_{40}]^{6-}$  (known as metatungstate and in which the protons are in the center of the cage) are normally metastable. Acidification of solutions containing paratungstates ultimately afforded  $\alpha\text{-}[\text{H}_2\text{W}_{12}\text{O}_{40}]^{6-}$ , but intermediates appear to include the partially characterized  $[\text{H}_7\text{W}_{11}\text{O}_{40}]^{7-}$ , which may be a lacunary species derived from  $[\text{H}_2\text{W}_{12}\text{O}_{42}]^{10-}$ ,  $[\text{W}_{10}\text{O}_{32}]^{4-}$  (sometimes known as tungstate-Y), and small amounts of  $\beta\text{-}[(\text{H}_2)\text{W}_{12}\text{O}_{40}]^{6-}$  (known previously as tungstate-X),  $\alpha\text{-}$  and  $\beta\text{-}[(\text{H})\text{W}_{12}\text{O}_{40}]^{7-}$ , in which the protons are in the center of the cage. Other isopolytungstates have been reported, including  $[(\text{H}_4)\text{W}_{12}\text{O}_{40}]^{4-}$ , in which the protons are thought to be in the center of the cage,  $[\text{H}_3\text{W}_6\text{O}_{22}]^{5-}$ , and  $[\text{HW}_5\text{O}_{19}]^{7-}$ .

In nonaqueous media,  $[\text{W}_6\text{O}_{19}]^{2-}$  and  $[\text{W}_{10}\text{O}_{32}]^{4-}$  are stable and have been characterized spectroscopically (particularly by  $^{183}\text{W}$  nmr), and  $[\text{H}_6\text{W}_{18}\text{O}_{60}]^{6-}$  exhibited reversible voltammetric behavior in acetonitrile.

Mixed metal isopolyanions incorporating vanadium,  $[\text{V}_x\text{W}_{6-x}\text{O}_{19}]^{(2+x)-}$  ( $x = 1-3$ ), the Keggin ions  $[(\text{V})\text{V}_x\text{W}_{12-x}\text{O}_{40}]^{(3+x)-}$  ( $x = 1-4$ ), and  $[\text{H}_2\text{W}_{11}\text{VO}_{40}]^{7-}$  have been described.  $^{51}\text{V}$  NMR spectral investigations of vanadate-tungstate mixtures revealed that  $[\text{WV}_9\text{O}_{28}]^{5-}$  existed at pH 5 and an isomer of  $[\text{V}_3\text{W}_3\text{O}_{19}]^{5-}$  at pH 6.5. From  $^{183}\text{W}$  and  $^{95}\text{Mo}$  NMR spectral studies, it was established that all possible mixtures of  $[(\text{Mo},\text{W})_7\text{O}_{24}]^{6-}$  existed but that only one molybdenum center could be substituted into  $[\text{H}_2\text{W}_{12}\text{O}_{42}]^{10-}$  and  $\alpha\text{-}[\text{H}_2\text{W}_{12}\text{O}_{40}]^{6-}$ .

### 9.2.2 Heteropolyanions

The Keggin-structure anion  $\alpha\text{-}[\text{XW}_{12}\text{O}_{40}]^{n-}$ , particularly the tungstophosphates and tungstosilicates, are the most frequently investigated because of the potential and real catalytic applications. The central heteroatoms, X, in the Keggin and isomeric anions  $[\text{XW}_{12}\text{O}_{40}]^{n-}$  include, in the  $\alpha$ -form (H)<sub>2</sub>, Be, B, Al, Ga, Si, Ge, P<sup>V</sup>, As<sup>V</sup>, V, Cr<sup>3+</sup>, Fe<sup>3+</sup>, Co<sup>2+,3+</sup>, Co<sup>1+,2+</sup>, and Zn, and in the  $\beta$  form (H)<sub>2</sub>, Al, Ga, Si, Ge, and P<sup>V</sup>. Unlike the situation in heteropolymolybdate chemistry, no capped heteropolytungstates have yet been reported.

Four of the possible six possible skeletal isomers having the Wells–Dawson structure, as exemplified by  $[\text{E}_2\text{W}_{18}\text{O}_{62}]^{6-}$  (E = P or As), have been structurally identified. The so-called ‘Preyssler’ anion was structurally identified as  $[(\text{Na}(\text{H}_2\text{O}))\text{P}_5\text{W}_{30}\text{O}_{110}]^{14-}$ , it being shown that the  $\text{Na}(\text{H}_2\text{O})^+$  group was tightly bound in the center of the cluster. However, under forcing conditions, the aqua-sodium cation could be replaced by  $\text{Ca}^{2+}$ , trivalent lanthanide cations and some tetravalent actinide cations, all of which have similar ionic radii

(ca. 1/Å). All of these anions exhibited reversible tungsten-based reduction behavior.

Lacunary version of the Keggin- and Dawson-type structures have been isolated and crystallographically characterized. In these species, up to three ‘octahedral W’ units may be extracted, generating species such as  $[\text{EW}_{11}\text{O}_{39}]^{n-}$ ,  $[\text{EW}_{10}\text{O}_{36}]^{n-}$ ,  $[\text{EW}_9\text{O}_{34}]^{n-}$ ,  $[\text{E}_2\text{W}_{17}\text{O}_{61}]^n$ , and  $[\text{E}_2\text{W}_{15}\text{O}_{56}]^{12-}$ . In an exceptional case,  $\alpha\text{-}[\text{P}_2\text{W}_{12}\text{O}_{48}]^{14-}$ , which has six W units extracted from the Wells–Dawson core, has been characterized. All of these lacunary anions have structures, in which no  $\text{WO}_6$  octahedral has more than two (cis) terminal oxygen atoms. As such, these species are particularly useful synthetic precursors for the incorporation of other metal ions, thereby reconstituting the idealized Keggin or Wells–Dawson structure. Species having one missing W unit, such as  $[\text{EW}_{11}\text{O}_{39}]^{n-}$  or  $[\text{E}_2\text{W}_{17}\text{O}_{61}]^{n-}$ , have generated a very large number of species, in which the inserted atom is a metal cation carrying a variety of terminal ligands, or in some case, no addition ligands. Such cluster complexes could be regarded as coordination compounds with the polyoxometallate group functioning as a tetra or pentadentate ligand. In such species, the polyoxometallate ligand appears to act as a  $\pi$ -acceptor species. Corresponding heteropolytungstates with two missing W units may be reconverted to Keggin structures, as in the conversion of  $[\text{SiW}_{10}\text{O}_{36}]^{8-}$  to  $[\text{SiW}_{10}\text{M}_2\text{O}_{40}]^{n-}$  where M = Mo, Mn<sup>III</sup>, Fe<sup>III</sup>, Ti( $\eta\text{-C}_5\text{H}_5$ )<sub>2</sub>, and a similar situation occurred with the trivacant lacunary anions,  $[\text{EW}_9\text{O}_{34}]^{n-}$  and  $[\text{P}_2\text{W}_{15}\text{O}_{56}]^{12-}$ . The magnetic properties of a number of metal complexes containing  $\text{M}^{\text{II}}\text{O}_6$  octahedra, such as  $[\text{PW}_9\text{O}_{34}\text{Ni}_4(\text{OH})_3(\text{H}_2\text{O})_6]^{4-}$  and  $[\text{Co}_7(\text{H}_2\text{O})_2(\text{OH})_2\{\text{PW}_9\text{O}_{34}\}_2(\text{W}_7\text{O}_{26})]^{16-}$ , have been measured.

A large number and variety of polytungstate complexes incorporate pairs of trivacant lacunary anions, which effectively sandwich three or four metal atoms. Typical examples include  $[\{\text{EW}_9\text{O}_{34}\}_2(\text{RQ})_3]^{n-}$  (E = P or Si; Q = Si or Sn),  $[\{\text{EW}_9\text{O}_{34}\}_2(\text{UO}_2)_2]^{n-}$  (E = P or Si),  $[\{\text{PW}_9\text{O}_{34}\}_2\text{Fe}^{\text{III}}_4(\text{H}_2\text{O})_2]^{n-}$ ,  $[\{\text{P}_2\text{W}_{15}\text{O}_{56}\}_2\text{Fe}^{\text{III}}_4(\text{H}_2\text{O})_2]^{12-}$ , and  $[\{\text{BiW}_9\text{O}_{33}\}_2\text{Cu}_3]^{n-}$ .

Polyoxo(thio)metallates have been prepared by incorporating thio-metal groups into lacunary anions, giving, for example,  $[\text{PW}_{11}\text{O}_{39}(\text{MX})]^{4-}$  (M = Nb, Ta; X = S, Se)  $[\text{SiW}_{10}\text{O}_{38}\text{M}_2\text{S}_2]^{6-}$  (M = Mo or W),  $[\{\text{PW}_{11}\text{O}_{39}\}_2\{\text{Mo}_2\text{S}_2(\text{OH})_2\text{O}_2\}]^{10-}$ ,  $[\{\text{PW}_9\text{O}_{234}\}_2\{\text{Mo}_2\text{S}_2(\text{OH})_2\text{O}_2\}_3]^{10-}$ , and  $[\{\text{SiW}_{11}\text{O}_{39}\}_2\{\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_3(\text{OH})_2\}]^{10-}$ .

### 9.2.3 Very Large Polyoxotungsten Anions

Composite anions have been constructed from assemblies of relatively simple, usually lacunary, polytungstate anions. Examples include  $[\text{Ln}_2(\text{H}_2\text{O})_2\{\text{SbW}_9\text{O}_{33}\}(\text{W}_5\text{O}_{18})_2]^{15-}$  (molar mass 5056; Ln = Y, Sm, Er),  $[\text{Ce}_4(\text{OH})_2(\text{H}_2\text{O})_9\{\text{P}_2\text{W}_{16}\text{O}_{59}\}_2]^{4-}$  (molar mass 8652),  $[\text{Ln}(\text{Ln}_2(\text{OH})(\text{H}_2\text{O})_{11}(\text{WO}_4)_4\{\text{AsW}_9\text{O}_{33}\}_4]^{20-}$  (molar mass 10 529; Ln = Ce, Nd,

Sm, Gd), and  $[\text{Ln}_{16}(\text{H}_2\text{O})_{36}(\text{WO}_4)_4(\text{W}_2\text{O}_6)_8\{\text{AsW}_9\text{O}_{33}\}_{12}(\text{W}_5\text{O}_{18})_4]^{76-}$  (molar mass 39 383).

### 9.3 Cluster Compounds Containing Chalcogenide Atoms

There are three main cluster types encountered in this group of important compounds: the incomplete cuboid  $\{\text{W}_3(\mu_3\text{-E})(\mu\text{-E})_3\}^{4+}$ , the sulfur-rich incomplete cuboid  $\{\text{W}_3(\mu_3\text{-E})(\mu, \mu'\text{-E})_3\}^{4+}$ , and the cuboid  $\{\text{W}_4(\mu_3\text{-E}_4)\}^{5+}$ .<sup>7</sup> These species are described as 'cuboidal' since this illustrates the best approximation in what are usually somewhat distorted structures.

#### 9.3.1 Trinuclear Clusters, $[\text{W}_3\text{E}_4]^{4+}$

The parent species  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  is well established and characterized (**80**) but an efficient synthesis was devised by heating  $[\text{W}_3\text{S}_4(\text{S}_4)_3(\text{NH}_3)_3]^{2-}$  with concentrated HCl, or by treatment of polymer  $[\{\text{W}_3\text{S}_7\text{Br}_4\}_n]$  with  $\text{H}_3\text{PO}_2$  in hot concentrated HCl. The core cluster  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  was structurally characterized in two salts, establishing the W–W bond length as 2.72 Å, identical to that in the analogous molybdenum cluster  $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ . All three mixed O/S clusters were prepared by comproportionation of  $[\text{NH}_4]_2[\text{WS}_4]$  with  $\text{K}_3[\text{W}_2\text{Cl}_9]$  in aqueous media.  $[\text{W}(\text{CO})_6]$  reacted with  $\text{Na}_2\text{S}$  in acetic anhydride, affording the  $\{\text{W}_3\text{O}_3\text{S}\}^{4+}$  core as the sole isolable product, and it was extracted by  $\text{NCS}^-$ , giving  $[\text{W}_3\text{O}_3\text{S}(\text{NCS})_9]^{5-}$  (W–W 2.61 Å).

While no fully chlorinated species  $[\text{W}_3\text{E}_4\text{Cl}_9]^{5-}$  (E = S or Se) have been detected, some  $\text{Cl}^-$  coordination can occur giving, for example,  $[\text{W}_3\text{E}_4\text{Cl}(\text{H}_2\text{O})_8]^{3+}$ ,  $[\text{W}_3\text{S}_4\text{Cl}_2(\text{H}_2\text{O})_7]^{2+}$ , and  $[\text{W}_3\text{S}_4\text{Cl}_3(\text{H}_2\text{O})_6]^+$ . Apparently no complexes containing  $\text{F}^-$ ,  $\text{Br}^-$  or  $\text{I}^-$  have been described. In  $[\text{W}_3\text{S}_4(\text{O}_2\text{CH})_9]^{5-}$  it was established crystallographically that the formate ligand was monodentate, whereas in  $[\text{W}_3\text{S}_4(\text{O}_2\text{C}_2\text{O}_2)_3(\text{H}_2\text{O})_3]^{2-}$  the oxalato ligand was bidentate. The pentanedionato species  $[\text{W}_3\text{E}_4(\text{acac})(\text{py})_3]^+$  (E = S or Se) were obtained by reaction of  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$  in dilute HCl with Hacac, followed by addition of pyridine and a precipitating anion

(usually  $\text{PF}_6^-$ ).  $^1\text{H}$  NMR spectral studies established the stereochemical rigidity of these species in solution, and cyclic voltammetric studies established that the clusters underwent two quasi-reversible reductions corresponding to the generation of species containing  $\text{W}^{\text{IV}}_2\text{W}^{\text{III}}$  and  $\text{W}^{\text{IV}}\text{W}^{\text{III}}_2$ . The species  $[\text{W}_3\text{S}_4(\text{acac})(\text{NH}_3)_3]^+$  has also been reported. Nitrilotriacetic acid ( $\text{H}_3\text{nta}$ ) reacted with mixed O/S clusters, affording species including  $[\text{W}_3\text{O}_3\text{S}(\text{Hnta})_3]^{2-}$ ,  $[\text{WO}_2\text{S}_2(\text{Hnta})_3]^{2-}$ , and  $[\text{WOS}_3(\text{Hnta})_3]^{2-}$ , and mixed metal clusters  $[\text{Mo}_2\text{WS}_4(\text{Hnta})_3]^{2-}$  and  $[\text{MoW}_2\text{S}_4(\text{Hnta})_3]^{2-}$  have also been characterized. These clusters undergo three consecutive one-electron reductions corresponding to the stepwise reduction of each metal center. Polyaminopolycarboxylic acids also formed complexes containing the  $\{\text{W}_4\text{S}_{4-n}\text{O}_n\}^{4+}$  cores. These included  $[\{\text{W}_3\text{S}_4\}_2(\text{egta})_3]^{4-}$  ( $\text{H}_4\text{egta}$  = ethyleneglycol-bis(2-aminoethyl)tetraacetic acid),  $[\{\text{W}_3\text{O}_3\text{S}\}_2(\text{egta})_3]^{4-}$ ,  $[\text{W}_3\text{S}_4(\text{ttha})]^{2-}$  ( $\text{H}_6\text{ttha}$  = triethylenetetraminehexaacetic acid),  $[\{\text{W}_3\text{S}_4\}_2(\text{ttha})_2]^{4-}$ , and  $[\{\text{W}_3\text{S}_4\}_2(\text{ttha})_3]^{10-}$ . The crystal-structure determination of a salt of  $[\{\text{W}_3\text{S}_4\}_2(\text{ttha})_2]^{4-}$  revealed that the ttha ligands were decadentate, being alternately hexadentate with respect to one  $\{\text{W}_3\text{S}_4\}$  cluster and tetradentate with respect to the other. Anionic clusters of similar complexity containing the  $\{\text{W}_3\text{O}_3\text{S}\}^{4+}$  core included  $[\text{W}_3\text{O}_3\text{S}(\text{obeta})_3]^{4-}$  ( $\text{H}_4\text{obeta}$  = oxybis(ethylamine)tetraacetic acid),  $[\{\text{W}_3\text{O}_3\text{S}\}_2(\text{obeta})_3]^{4-}$ ,  $[\{\text{W}_3\text{O}_3\text{S}\}_2(\text{bdta})_3]^{4-}$  ( $\text{H}_4\text{bdta}$  = 1, 4-butylenediaminetetraacetic acid), and  $[\{\text{W}_3\text{O}_3\text{S}\}_2(\text{pdta})_3]^{4-}$  ( $\text{H}_4\text{pdta}$  = 1, 3-propylenediaminetetraacetic acid). In studies of the reactions of  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$  (E = S or Se) with  $\text{NCS}^-$ , it was concluded that the first product formed involved an S-bonded thiocyanate isomer, but this later isomerized to a more stable N-bonded form,  $[\text{W}_3\text{E}_4(\text{NCS})_9]^{5-}$ .  $[\text{W}_3\text{S}_4(\text{NCS})_9]^{5-}$  was obtained either by heating polymeric  $[\{\text{W}_3\text{S}_7\text{Br}_4\}_n]$  in a melt of KNCS or by reaction of  $\text{NCS}^-$  with  $[\text{W}_3\text{S}_7\text{Br}_6]^{2-}$  in refluxing acetonitrile. Reaction of  $[\{\text{W}_3\text{Se}_7\text{Br}_4\}_n]$  with KNCS afforded a mixture of all possible  $[\text{W}_3\text{S}_n\text{Se}_{4-n}(\text{NCS})_9]^{5-}$ , but these were eventually converted into  $[\text{W}_3\text{S}_4(\text{NCS})_9]^{5-}$ .

Polymeric  $[\{\text{W}_3\text{S}_7\text{Br}_4\}_n]$  reacted slowly with  $(\text{NH}_4)_2\text{S}_x$  at room temperature giving black needles of  $[\text{NH}_4]_2[\text{W}_3\text{S}_4(\text{S}_4)_3(\text{NH}_3)_3]\cdot\text{H}_2\text{O}$ . The tetrasulfido ligand was bidentate and the W–S bond distances were rather long (2.5 Å), explaining why this species reacted with concentrated HCl easily giving  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ .

Treatment of  $[\{\text{W}_3\text{S}_7\text{Cl}_4\}_n]$  with  $\text{PPh}_3$  in thf afforded  $[\text{W}_3\text{S}_4\text{Cl}_4(\text{PPh}_3)_3(\text{H}_2\text{O})_2]\cdot 3\text{thf}$ . However, reaction of  $\text{PEt}_3$  with  $[\{\text{W}_3\text{S}_7\text{Br}_4\}_n]$  in thf afforded  $[\text{W}_3\text{S}_4\text{Br}_4(\text{PEt}_3)_3\{\text{P}(\text{O})\text{HEt}_2\}_2(\text{H}_2\text{O})]$ , in which partial P–C bond fission and phosphine oxidation had occurred. With bidentate phosphines (dmpe, dppe),  $[\{\text{W}_3\text{S}_7\text{X}_4\}_n]$  (X = Cl or Br) was converted to  $[\text{W}_3\text{S}_4\text{X}_3(\text{dmpe})_3]^+$  and  $[\text{W}_3\text{S}_4\text{X}_3(\text{dppe})_3]^+$ . In the course of these reactions, mixed halide clusters  $[\text{W}_3\text{S}_4\text{Cl}_2\text{Br}(\text{dmpe})_3]^+$  and  $[\text{W}_3\text{S}_4\text{ClBr}_2(\text{dmpe})_3]^+$  could be detected. The mixed sulfido/selenido cluster  $[\text{W}_3\text{S}_x\text{Se}_{4-x}(\text{NCS})_9]^{5-}$  reacted with dppe giving  $[\text{W}_3\text{S}_x\text{Se}_{4-x}(\text{NCS})_3(\text{dppe})_3]^+$ , and  $[\text{W}_3\text{Se}_4\text{Br}_3(\text{dppe})_3]^+$  was obtained directly from  $[\{\text{W}_3\text{Se}_7\text{Br}_4\}_n]$ .

Reaction of  $[\text{W}_3\text{S}_4\text{Cl}_3(\text{dmpe})_3]^+$  with  $\text{BH}_4^-$  gave the pink air-stable trihydrido complex  $[\text{W}_3\text{S}_4\text{H}_3(\text{dmpe})_3]^+$ .

Treatment of polymeric  $[\{\text{W}_3\text{Se}_7\text{Br}_4\}_x]$  with hot aqueous KCN afforded  $[\text{W}_3\text{Se}_4(\text{CN})_9]^{5-}$ , which could be electrochemically reduced in a one-electron step, affording  $[\text{W}_3\text{Se}_4(\text{CN})_9]^{6-}$ , containing the  $\text{W}^{\text{IV}}_2\text{W}^{\text{III}}$  core.

### 9.3.2 Trinuclear Complexes, $[\text{W}_3\text{E}_7]^{4+}$

The polymeric clusters  $[\{\text{W}_3\text{E}_7\text{X}_4\}_x]$  (E = S or Se; X = Cl or Br) were prepared by heating the elements in a sealed tube at ca. 350 °C. The structure of  $[\{\text{W}_3\text{S}_4\text{Br}_4\}_x]$  consists of  $\text{W}_3(\mu_3\text{-S})(\mu_2\text{-S}_2)_3^{4+}$  units bridge by four Br atoms forming an extended zigzag structure. The corresponding selenides are thought to have the same basic structure. The bridging  $\text{S}_2$  groups are asymmetrically coordinated and since the metal atoms are formally in oxidation state IV, there are six electrons available to form three single metal–metal bonds in the triangle. Under certain conditions, the halide ion can cleave the bridges giving  $[\text{W}_3\text{E}_7\text{X}_6]^{2-}$  (**81**) (X = Cl or Br) and the clusters can be aquated to form relatively stable ions  $[\text{W}_3\text{E}_7(\text{H}_2\text{O})_6]^{4+}$ . The structural dimensions of the  $\{\text{W}_3\text{S}_7\}^{4+}$  core are very similar to those of its molybdenum analog.

Treatment of  $[\{\text{W}_3\text{Se}_7\text{X}_4\}_x]$  with  $\text{PPh}_4\text{X}$  (in melts) or  $\text{Et}_4\text{NX}$  (in vibration mills) afforded  $[\text{W}_3\text{Se}_7\text{X}_6]^{2-}$ . Treatment of the hexahalides with  $\text{NaS}_2\text{CNR}_2$  afforded  $[\text{W}_3\text{Se}_4(\text{S}_2\text{CNR}_2)_3]^+$ , in which there are strong interactions between the axial Se atom and an S atom of the dithiocarbamate ligand. When  $[\text{W}(\text{CO})_6]$  was refluxed with selenium and tetraethylthiuram disulfide in 1,2-dichlorobenzene, red  $[\{\text{W}_3\text{Se}_7(\text{S}_2\text{CNEt}_2)_3\}_2\text{Se}]$  was formed. Treatment of  $[\text{W}_3\text{Se}_7\text{Br}_6]^{2-}$  with  $[\text{S}_2\text{P}(\text{OEt})_2]^-$  in acetonitrile afforded the dithiophosphato cluster  $[\text{W}_3\text{Se}_7\{\text{S}_2\text{P}(\text{OEt})_2\}_3]^-$  and the 1,10-phenanthroline (phen) cluster  $[\text{W}_3\text{Se}_7(\text{phen})_3]^{4+}$  was obtained by melting  $[\{\text{W}_3\text{Se}_7\text{X}_4\}_x]$  with the bidentate heterocycle. Treatment of  $[\text{W}_3\text{S}_7\text{X}_6]^{2-}$  (X = Cl or Br) with  $\text{PPh}_3\text{Se}$  afforded  $[\text{W}_3\text{S}(\text{SSe})_3\text{X}_6]^{2-}$  and reaction of this with  $\text{KNCS}$ , in the presence of an excess of  $\text{KNCS}$ , gave  $[\text{W}_3\text{S}(\text{SSe})_3(\text{NCS})_6]^{2-}$ . The aqua cluster  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  reacted with  $\text{P}_4\text{S}_{10}$  in ethanolic HCl to give  $[\text{W}_3\text{Se}(\text{SSe})_3\{\text{S}_2\text{P}(\text{OEt})_2\}_3]^+$ .

### 9.3.3 Tetranuclear cubic $\{\text{W}_4\text{E}_4\}^{5+}$ Clusters

Brown-red  $[\text{W}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{6+}$  was prepared by the reaction of  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_6]^{4+}$  with  $[\text{W}(\text{CO})_6]$  in aqueous HCl under hydrothermal conditions. This species is presumed to have a structure very similar to its molybdenum analog, viz. consisting of two interpenetrating  $\text{W}_4$  and  $\text{S}_4$  tetrahedra of different sizes, leading to a distorted pseudo-cubic geometry. The hexa-cation was electrochemically reduced to  $[\text{W}_4\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ , the potentials indicating its oxidative instability.

Mixed metal clusters were obtained by reaction of  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ ,  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$ ,  $[\text{MoW}_2\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ , and  $[\text{Mo}_2\text{WS}_4(\text{H}_2\text{O})_9]^{4+}$  with  $[\text{Mo}_2\text{Cl}_8]^{4-}$ , giving  $[\text{MoW}_3\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ ,  $[\text{MoW}_3\text{Se}_4(\text{H}_2\text{O})_{12}]^{5+}$ ,  $[\text{Mo}_2\text{W}_2\text{S}_4(\text{H}_2\text{O})_{12}]^{5+}$ , and  $[\text{Mo}_3\text{WS}_4(\text{H}_2\text{O})_{12}]^{5+}$ . Oxidation of these pentacationic species by  $[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$  initially afforded the hexacations but these decomposed by loss of one W atom, for example, in the process  $[\text{MoW}_3\text{S}_4(\text{H}_2\text{O})_{12}]^{5+} \rightarrow [\text{MoW}_3\text{S}_4(\text{H}_2\text{O})_{12}]^{6+} \rightarrow [\text{MoW}_2\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ . Electrochemical studies of these pentacationic mixed metal cubic clusters revealed two reversible redox processes corresponding to a one-electron reduction and a one-electron oxidation.

When  $\text{WTe}_2$  was heated with KCN,  $[\text{W}_4\text{Te}_4(\text{CN})_{12}]^{6-}$  was formed, while in a  $\text{KNCS}$  melt, chalcogen exchange occurred, leading to  $[\text{W}_4\text{S}_4(\text{CN})_{12}]^{6-}$ . These species have been structurally characterized and it was established that the symmetry of the cluster core was sensitive to the nature of the counter ion. The core clusters in the  $\text{NH}_6^+$  salts had ideal  $T_d$  symmetry ( $d_{\text{W-W}}$  2.85 Å) in the  $[\text{KCs}_5]^{6+}$  salt  $C_1$  symmetry ( $d_{\text{W-W}}$  2.80–90 Å), and in the  $\text{K}^+$  salt  $C_2$  symmetry ( $d_{\text{W-W}}$  2.83–2.91 Å).  $\text{K}_6[\text{W}_4\text{Se}_4(\text{CN})_{12}] \cdot 6\text{H}_2\text{O}$  exhibited a cuboidal core with  $C_{2v}$  symmetry ( $d_{\text{W-W}}$  2.88 Å). The complexes were electrochemically active, showing two reversible or quasi-reversible reduction processes, one corresponding to the formation of 7(–) and 8(–) species. Despite the distortions observed in the solid state, the  $^{77}\text{Se}$ ,  $^{125}\text{Te}$  and  $^{183}\text{W}$  NMR studies on  $[\text{W}_4\text{E}_4(\text{CN})_{12}]^{6-}$  indicated the equivalence of metal and chalcogen atoms in solution.

In a solvento-thermal reaction involving  $[\text{W}(\text{CO})_6]$ ,  $\text{K}_2\text{S}_4$ , and 1,2-diaminoethane (en) at 300 °C, the slightly electron-deficient (54-valence electron) black-red cluster  $[\text{W}_4\text{S}_4(\text{en})_4(\text{S}_4)]\text{S}$  was formed. This species contains a  $\text{W}_4\text{S}_4$  cuboidal skeleton ( $d_{\text{W-W}}$  2.80–2.88 Å) and  $\text{S}^{2-}$  as a counter-anion. While the W–S bonds involving the  $\mu_3$ -bridges is 2.36–2.41 Å, the formal  $\text{W}=\text{S}$  bond lengths are 2.54 Å, rather longer than expected. This suggested that the species might be better formulated as the 58-electron  $[\text{W}_4\text{S}_4(\text{en})_4(\text{SH})_4]\text{S}$ , which was more consistent with the geometry of the cluster but no S–H vibrational bands were detected by IR spectroscopy. The species was paramagnetic, obeying the Curie–Weiss law, with  $\mu = 2.67$  BM at 400 K.

### 9.3.4 Raft-like Clusters $[W_4(\mu_3-S)_2(\mu-S)_4]^2+$

Treatment of *cis*- $W(N_2)_2(PMe_2Ph)_4$  with two equivalents of  $(Me_3Si)_2S$  in methanol afforded  $[W_4(\mu_3-S)_2(\mu-S)_4(SH)_2(PMe_2Ph)_6]$ . This 58-electron cluster has sufficient electrons (10) to form five W–W bonds, including one between the hinge atoms (see (82)) ( $d_{W-W}$  2.81–2.84 Å), and the presence of S–H groups was confirmed crystallographically. Reaction of this complex with  $SnCl_2$  in thf effected Cl/S–H group exchange, giving  $[W_4(\mu_3-S)_2(\mu-S)_4Cl_2(PMe_2Ph)_6]$ . Oxidation of this species by  $Ag^+$  afforded  $[W_4(\mu_3-S)_2(\mu-S)_4Cl_2(PMe_2Ph)_6]^2+$ , a 56-electron cluster that retained its raft-like connectivity, although the core no longer retained  $C_{2h}$  symmetry but was distorted, with a pair of opposing W–W bonds elongated to 2.94 Å, another pair shortened to 2.74 Å, and only the W–W hinge remaining relatively unperturbed at 2.83 Å. Reduction of  $[W_4(\mu_3-S)_2(\mu-S)_4Cl_2(PMe_2Ph)_6]$  by sodium amalgam afforded  $[W_4(\mu-S)_6(PMe_2Ph)_4]$ , which contains an adamantane-like core. There are 12 electrons in this  $W^{III}$  species ( $d_{W-W}$  2.63 Å), the basic coordination geometry around each metal atom (neglecting the formal W–W bond) being essentially tetrahedral.

### 9.3.5 Heterometallic Derivatives of $[W_3E_4(H_2O)_9]^{4+}$

The incomplete cubes  $[W_3E_4(H_2O)_9]^{4+}$  ( $E = S, Se$ ) reacted with metal ions to generate cuboidal species. These are generally of three types, shown in (83), (84), and (85). The cluster (83) utilizes a heterometal atom with variable coordination preferences (usually octahedral or tetrahedral), constituting a cuboidal species. However when  $M'$  prefers tetrahedral geometry, the edge-linked double cube (84) can be formed. The incomplete cube can also function as a pair of tridentate 'ligands', generating a corner-shared cube (85).

The conversion of (83) to (84) occurred when the anions accompanying the reaction were normally noncoordinating, such as  $ClO_4^-$  or  $p\text{-MeC}_6\text{H}_4\text{SO}_3^-$ , and regeneration of (83) would occur when ligands such as  $CO$ ,  $PR_3$ ,  $Cl^-$ , or  $NCS^-$  were added and attached to  $M'$ . In general, the W–W distances in these species were relatively short (2.5–2.8 Å) and while relatively short W– $M'$  bonds (ca. 2.7 Å) were characteristic when  $M'$  was a transition metal in (84) and (85), long nonbonding interactions (>3.5 Å) were typical features of (83) and (84) when  $M'$  was a metal from groups 12 or 13.

While the mixed metal clusters  $[Mo_3WS_4(H_2O)_9]^{4+}$  and  $[WMo_3S_4(H_2O)_9]^{4+}$  were described earlier, there are no reported examples of  $[CrW_3S_4(H_2O)_9]^{4+}$ . A similar situation exists with Mn and Re. No clusters containing Fe, Ru, Os, or Co have been reported but there is evidence that  $[W_3S_4(H_2O)_9]^{4+}$  reacted with  $RhCl_3$  in 4M HCl, although the product was not characterized. Reaction of metallic Ni with  $W_3S_4(H_2O)_9]^{4+}$  afforded green  $[W_3NiS_4(H_2O)_{10}]^{4+}$  [(83,  $M' = Ni(H_2O)$ ], and the mixed Mo/W clusters  $[MoW_2NiS_4(H_2O)_{10}]^{4+}$  and  $[Mo_2WNiS_4(H_2O)_{10}]^{4+}$  were also isolated. In these three species, the  $Ni^{II}$  center adopted tetrahedral geometry. Crystallization of the tungsten-rich clusters resulted in edge-linked double cubes  $[W_3NiS_4(H_2O)_9]_2^{8+}$  ( $d_{Ni-Ni}$  2.56 Å) and  $[MoW_2NiS_4(H_2O)_9]_2^{8+}$  ( $d_{Ni-Ni}$  2.55 Å), (84).  $[W_3NiS_4(H_2O)_{10}]^{4+}$  reacted with  $CO$  giving  $[W_3Ni(CO)S_4(H_2O)_9]^{4+}$ . While no clusters containing Pd have been described,  $[W_3S_4(H_2O)_9]^{4+}$  reacted with  $[PtCl_4]^{2-}$  giving the edge-linked double cube  $[W_3PtS_4(H_2O)_9]_2^{8+}$ .

Reaction of  $[W_3S_4(H_2O)_9]^{4+}$  with copper metal afforded the green air-sensitive  $[W_3CuS_4(H_2O)_{10}]^{5+}$ , but no evidence for  $[W_3CuS_4(H_2O)_{10}]^{4+}$  could be found.  $[W_3S_4X_3(dmpe)_3]^+$  ( $X = Cl$  or  $Br$ ) reacted with  $Cu^I$  halides or with  $[Cu(NCMe)_4]^+$  in the presence of  $X^-$  to give  $[W_3(CuX)S_4X_3(dmpe)_3]^+$  ( $d_{W-W}$  2.78 Å;  $d_{Cu-W}$  2.88 Å). Dithiophosphato derivatives such as  $[W_3(CuI)S_4(\mu-O_2CCl_3)\{S_2P(OEt)_2\}_3(NCMe)]$  and  $[W_3(CuI)S_4(\mu-O_2CMe)\{S_2P(OEt)_2\}_3(py)]$  were also prepared. Reaction of  $[Mo_2WS_4(\mu-S_2PR_2)(S_2PR_2)_3]$  with  $CuI$  in the presence of pyridine afforded  $[Mo_2W(CuI)(\mu-S_2PR_2)(S_2PR_2)_3(py)]$  ( $R = Et, Pr^n$ ).

Treatment of  $[W_3S_4(H_2O)_9]^{4+}$  with mercury afforded the purple corner-shared double cube  $W_6Hg_2S_8(H_2O)_{18}]^{8+}$  (85). However, no reaction was observed between the trinuclear tungsten species and metallic Ga or  $GaCl_3$  reduced by  $NaBH_4$ . However, when metallic In was added to  $[W_3E_4(H_2O)_9]^{4+}$ ,  $[W_3InE_4(H_2O)_{12}]^{5+}$  was formed (83;  $E = S$ , dark blue,  $E = Se$ , blue–green). When equimolar

amounts of  $[\text{W}_3\text{InS}_4(\text{H}_2\text{O})_{12}]^{5+}$  and  $[\text{Mo}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  were mixed, rapid and quantitative  $\text{In}^+$  transfer took place, giving  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  and  $[\text{Mo}_3\text{InS}_4(\text{H}_2\text{O})_{12}]^{5+}$ . Treatment of  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ) with  $\text{GeO}$  or  $\text{GeO}_2/\text{H}_3\text{PO}_2$ , the single cubes  $[\text{W}_3\text{GeE}_4(\text{H}_2\text{O})_{12}]^{6+}$  (**83**), only were formed. However, the double cubes  $[\text{W}_6\text{GeE}_8(\text{H}_2\text{O})_{18}]^{8+}$ , (**85**), were obtained by reduction of  $[\text{W}_3\text{GeE}_4(\text{H}_2\text{O})_{12}]^{6+}$  ( $d_{\text{W-W}} 2.67 \text{ \AA}$  when  $\text{E} = \text{S}$ ) by  $\text{BH}_4^-$  in the presence of a further equivalent of  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$ . Solution studies of  $[\text{W}_3\text{GeS}_4(\text{H}_2\text{O})_{12}]^{6+}$  indicated that the Ge center was coordinated by three  $\text{H}_2\text{O}$  ligands, which could be replaced by  $\text{Cl}^-$  giving  $[\text{W}_3(\text{GeCl}_3)\text{S}_4(\text{H}_2\text{O})_{12}]^{3+}$ . Reaction of metallic tin (as shot) with  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  gave only the single cube  $[\text{W}_3\text{SnS}_4(\text{H}_2\text{O})_{12}]^{6+}$ . However,  $\text{BH}_4^-$  reduction of  $[\text{W}_3(\text{SnCl}_3)\text{S}_4(\text{H}_2\text{O})_9]^{3+}$  in the presence of  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  afforded the double cube  $[\text{W}_6\text{SnS}_8(\text{H}_2\text{O})_{18}]^{8+}$  (**85**,  $\text{M}' = \text{Sn}$ ). This method of reductive coupling was also employed to make  $[\text{Mo}_3\text{W}_3\text{SnS}_8(\text{H}_2\text{O})_{18}]^{8+}$  and  $[\text{Mo}_3\text{W}_3\text{SnS}_4\text{Se}_4(\text{H}_2\text{O})_{18}]^{8+}$ , the latter being obtained in a reaction involving  $\text{BH}_4^-$  reduction of  $[\text{Mo}_3(\text{SnCl}_3)\text{S}_4(\text{H}_2\text{O})_9]^{3+}$  in the presence of  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$ . These double cubes could be oxidized by  $\text{O}_2$  or  $[\text{Fe}(\text{H}_2\text{O})_6]^{3+}$  to  $[\text{W}_3\text{SnE}_4(\text{H}_2\text{O})_{12}]^{6+}$  and then, with an excess of oxidant, to  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$  and  $\text{Sn}^{\text{IV}}$ . Treatment of  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  with Pb shot afforded the air-sensitive wine-red  $[\text{W}_6\text{PbSe}_8(\text{H}_2\text{O})_{18}]^{8+}$  (**85**,  $\text{M}' = \text{Pb}$ ), but no reaction occurred with  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$ . No single cubes of the type  $[\text{W}_3\text{PbE}_4(\text{H}_2\text{O})_{12}]^{6+}$  have been reported but treatment of  $[\text{W}_3\text{S}_4(\text{H}_2\text{O})_9]^{4+}$  with  $\text{PbI}_3^-$  in the presence of  $[\text{S}_2\text{P}(\text{OEt})_2]^-$  in pyridine-based media afforded  $[\text{W}_3(\text{PbI}_3)\text{S}_4\{\text{S}_2\text{P}(\text{OEt})_2\}_3(\text{py})_3]$ .

Gray arsenic did not react with  $[\text{W}_3\text{E}_4(\text{H}_2\text{O})_9]^{4+}$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ) but with  $\text{NaAsO}_2$  in the presence of  $\text{H}_3\text{PO}_2$ , red  $[\text{W}_6\text{AsSe}_8(\text{H}_2\text{O})_{18}]^{8+}$  (**85**,  $\text{M}' = \text{As}^0$ ) was formed. No single cubes containing As were detected, but oxidation of the double cube afforded  $\text{As}^{\text{III}}$  and  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$ . Treatment of  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  with  $\text{SbCl}_3$  or with Sb shot in the presence of  $\text{HCl}$  afforded yellow-brown  $[\text{W}_3(\text{SbCl}_3)\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  (**83**,  $\text{M}' = \text{SbCl}_3$ ). The dithiophosphate complex  $[\text{W}_3(\text{SbI}_3)\text{S}_4(\text{OAc})\{\text{S}_2\text{P}(\text{OEt})_2\}_3(\text{dmf})]$  was also prepared, and the  $\text{SbCl}_3$  group in  $[\text{W}_3(\text{SbCl}_3)\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  could be readily exchanged with  $\text{SnCl}_3^-$ . Reaction of  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  with  $\text{SbCl}_3$  and  $\text{H}_3\text{PO}_2$  gave the green-blue double cube  $[\text{W}_6\text{SbSe}_8(\text{H}_2\text{O})_{18}]^{8+}$  (**85**,  $\text{M}' = \text{Sb}^0$ ). Like its arsenic analog, this species could be oxidized with degradation to  $\text{Sb}^{\text{III}}$  and the precursor cluster. Reduction of  $\text{Bi}^{\text{III}}$  citrate by  $\text{H}_3\text{PO}_2$  in the presence of  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$  afforded the green-blue  $[\text{W}_6\text{BiSe}_8(\text{H}_2\text{O})_{18}]^{8+}$  (**85**,  $\text{M}' = \text{Bi}^0$ ), which was oxidized to regenerate  $\text{Bi}^{\text{III}}$  and  $[\text{W}_3\text{Se}_4(\text{H}_2\text{O})_9]^{4+}$ . The dithiophosphato cluster  $[\text{W}_3(\text{BiI}_3)\text{S}_4(\text{OAc})\{\text{S}_2\text{P}(\text{OEt})_2\}_3(\text{H}_2\text{O})]$  has also been characterized.

### 9.3.6 Octahedral Clusters, $\text{W}_6\text{E}_8$

Clusters of this type are found, with Mo, in the Chevrel phases  $\text{Mo}_6\text{E}_8$  ( $\text{E} = \text{S}$ ,  $\text{Se}$  or  $\text{Te}$ ) and in the ternary phases

$\text{M}'\text{Mo}_6\text{E}_8$ , but no such solid-state analogs containing tungsten have been confirmed. However, reaction of  $[\{\text{W}_6\text{Cl}_{12}\}_n]$  with  $\text{NaSH}$  and  $\text{OBU}^{n-}$  in pyridine afforded the dark red 20-electron cluster  $[\text{W}_6\text{S}_8(\text{py})_6]$  if the molar ratio of  $\text{W}:\text{S}$  was at least 1:12. This species was diamagnetic and insoluble, although single crystals could be obtained under special conditions. The cluster has an octahedral core of W atoms, each triangular face being bridged by S, the pyridine ligands binding terminally to the metal centers. If the  $\text{W}:\text{S}$  molar ratios were set at 1:8 and the reaction took longer, the insoluble red 22-electron cluster  $[\text{W}_6\text{S}_6\text{Cl}_2(\text{py})_6]$  was produced and if the molar ratio was maintained between 1:6 and 1:8, and using shorter reactions times, the red soluble 24-electron cluster  $[\{\text{W}_6\text{Cl}_6\text{S}_2\}\text{Cl}_2(\text{py})_6]\cdot 5\text{py}$  was generated. However, if pyridine was replaced by its 4-butyl analog,  $\text{Bu}^i\text{py}$ , and if  $[\text{Bu}_4\text{N}]_2[\text{W}_6\text{Cl}_{14}]$  was used in place of  $[\{\text{W}_6\text{Cl}_{12}\}_n]$ , the orange soluble  $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_6]$  was formed. The pyridine could be substituted by piperidine or  $\text{PET}_3$ , and  $[\text{W}_6\text{S}_8(\text{PET}_3)_6]$  could also be generated by reductive dimerization of  $[\text{W}_3\text{S}_4\text{Cl}_4(\text{PET}_3)_n]$  ( $n = 3$  or  $4$ ) using Mg in thf.

The clusters  $[\text{W}_6\text{S}_8\text{L}_6]$  ( $\text{L} = \text{PET}_3$ ,  $\text{Bu}^i\text{py}$ ) could be oxidized by ferrocenium cation to give the green paramagnetic 19-electron species  $[\text{W}_6\text{S}_8\text{L}_6]^+$  ( $\text{L} = \text{PET}_3$ ,  $\mu = 1.71 \text{ BM}$ ;  $\text{L} = \text{Bu}^i\text{py}$ ,  $\mu = 1.60 \text{ BM}$ ). The structures of the neutral and cationic  $[\text{W}_6\text{S}_8(\text{PET}_3)_6]^z$  ( $z = 0$  or  $+1$ ) showed that oxidation only marginally increased the W-W distances in the cluster (ca.  $2.68 \text{ \AA}$  in both species). Treatment of  $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_6]$  with  $\text{CN}^-$  afforded  $[\text{W}_6\text{S}_8(\text{CN})_6]^{6-}$  but with  $\text{P}(\text{C}_6\text{H}_{11})_3$ , only partial substitution could occur, affording *cis*- $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_2\{\text{P}(\text{C}_6\text{H}_{11})_3\}_4]$ .  $[\text{W}_6\text{S}_8\{\text{P}(\text{C}_6\text{H}_{11})_3\}_6]$  could be obtained from  $[\text{W}_6\text{S}_8(\text{NH}_2\text{Bu}^n)_6]$ . Prolonged heating of *cis*- $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_2\{\text{P}(\text{C}_6\text{H}_{11})_3\}_4]$  in benzene afforded a mixture of redistribution products, *fac*- and *mer*- $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_3\{\text{P}(\text{C}_6\text{H}_{11})_3\}_3]$ , *cis*- and *trans*- $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})_2\{\text{P}(\text{C}_6\text{H}_{11})_3\}_4]$ , and  $[\text{W}_6\text{S}_8(\text{Bu}^i\text{py})\{\text{P}(\text{C}_6\text{H}_{11})_3\}_5]$ .

Red  $[\text{W}_6\text{Se}_8\text{L}_6]$  ( $\text{L} = \text{piperidine}$  or  $\text{pyridine}$ ) were obtained by reaction of  $[\{\text{W}_6\text{Cl}_{12}\}_n]$ ,  $\text{Na}_2\text{Se}$  and  $\text{L}$  over several days. However, reaction with  $\text{PET}_3$  ( $\text{W}:\text{Se}$  ratio 1:8) afforded the red-brown 20-electron species  $[\text{W}_6\text{Se}_7\text{Cl}(\text{PET}_3)_6]^+$  (counter-anion  $\text{Cl}^-$ ). The Se and Cl atoms were randomly distributed over the eight possible positions ( $d_{\text{W-W}} 2.70 \text{ \AA}$ ). If  $\text{K}_2\text{Se}$  replaced  $\text{Na}_2\text{Se}$ , the  $\text{W}:\text{Se}$  ratio being 1:10,  $[\text{W}_6\text{Se}_{6.4}\text{Cl}_{1.6}(\text{PET}_3)_6]^+$  (as  $\text{Cl}^-$ ) was formed, this cation being shown to be a mixture of diamagnetic 20-electron  $[\text{W}_6\text{Se}_7\text{Cl}(\text{PET}_3)_6]^+$  and paramagnetic 21-electron  $[\text{W}_6\text{Se}_6\text{Cl}_2(\text{PET}_3)_6]^+$  in the ratio 2:3.

Reaction of  $[\{\text{W}_6\text{Cl}_{12}\}_n]$  with  $\text{Na}_2\text{Te}$  in refluxing piperidine or pyridine afforded the dark blue 20-electron  $[\text{W}_6\text{Te}_8(\text{pip})_6]\cdot 6\text{pip}$  ( $\text{W-W } 2.74 \text{ \AA}$ ) and the 21-electron  $[\text{Na}(\text{py})_6][\text{W}_6\text{Te}_8(\text{py})_6]\cdot \text{py}$  ( $d_{\text{W-W}} 2.72\text{--}2.75 \text{ \AA}$ ). Treatment of the piperidine cluster with pyridine afforded black  $[\text{W}_6\text{Te}_8(\text{py})_6]$  and of this with  $\text{PET}_3$  dark purple  $[\text{W}_6\text{Te}_8(\text{PET}_3)_6]$  ( $d_{\text{W-W}} 2.77 \text{ \AA}$ ).

## 1 INTRODUCTION

This article surveys the organometallic chemistry of tungsten in a systematic manner according to the various types of complexes known to contain tungsten–carbon bonds. Within each category of complex, the material is generally presented in the following order: common methods of synthesis of these complexes, their characteristic physical properties, and their representative chemical properties. The latter are usually illustrated by examples taken from the literature published since 1992, the final year of coverage by the first edition of the Encyclopedia of Inorganic Chemistry. Other articles in the current encyclopedia also cover some aspects of this chemistry, most notably alkene and alkyne metathesis reactions mediated by organotungsten complexes (see *Organic Synthesis Using Metal-mediated Metathesis Reactions*), the organometallic chemistry of di- and polynuclear tungsten complexes (see *Dinuclear Organometallic Cluster Complexes*), and tungsten compounds containing main group element ligands (see *Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements*).

Consequently, these topics are not specifically discussed in this article, which focuses primarily on the chemistry of mononuclear tungsten complexes containing organic ligands.

## 2 TUNGSTEN COMPLEXES CONTAINING CARBONYL, ISOCYANIDE, AND CYANIDE LIGANDS

### 2.1 Tungsten–Carbonyl Complexes

W(CO)<sub>6</sub> continues to be the most ubiquitous and readily available low-valent organometallic complex of tungsten (see *Carbonyl Complexes of the Transition Metals*), and it serves as a convenient entry point into much of the organometallic chemistry described in this chapter. One or more of its CO ligands may be replaced with neutral donors to form carbonyl compounds (see *Carbonyl Compound*) of the type W(CO)<sub>6–n</sub>(L)<sub>n</sub> (L = Lewis base). The homoleptic (see *Homoleptic Compound*) carbonyl anions [W(CO)<sub>5</sub>]<sup>2–</sup> and [W(CO)<sub>4</sub>]<sup>4–</sup> have been prepared by chemical reduction of suitable carbonyl compounds,<sup>1</sup> and the di- and tritungsten carbonyls, [W<sub>2</sub>(CO)<sub>10</sub>]<sup>2–</sup> (**1**) and [W<sub>3</sub>(CO)<sub>14</sub>]<sup>2–</sup>, containing W–W bonds have also been described.<sup>2,3</sup> The photochemistry of (**1**), which results in the formation of the highly reducing 19e radical [W(CO)<sub>5</sub>(S)]<sup>–</sup> upon irradiation in donor solvents, S (e.g. S = MeCN, THF), has been the topic of a recent review.<sup>2</sup> Treatment of W(CO)<sub>6</sub> with HF/SbF<sub>5</sub> in the presence of CO results in a remarkable 2e oxidation process and leads to the isolation of the cationic, seven-coordinate carbonyl complex [W(CO)<sub>6</sub>( $\eta^1$ -FSbF<sub>5</sub>)] [Sb<sub>2</sub>F<sub>11</sub>], that is, [(**2**)] [Sb<sub>2</sub>F<sub>11</sub>].<sup>4</sup>

The substitution of carbonyl ligands in W(CO)<sub>6</sub> may be effected either thermally or photochemically. Among the more important reactions from a synthetic standpoint are those of W(CO)<sub>6</sub> with nitriles (RCN) to generate *fac*-W(CO)<sub>3</sub>(RCN)<sub>3</sub> (**3**) (equation 1), the nitrile ligands of which may be displaced by other Lewis bases (see *Lewis Acids & Bases*) under mild conditions.<sup>5</sup> The reactions of W(CO)<sub>6</sub> with the cyclopentadienyl (see *Cyclopentadienyl*) reagents MCp' (M = Li, Na, K; Cp' = Cp,

Cp\*, etc.) afford anionic  $[\text{Cp}'\text{W}(\text{CO})_3]^-$  derivatives (4)<sup>6,7</sup> (equation 2) that have been used to prepare complexes such as  $\text{Cp}'\text{W}(\text{CO})_2(\text{NO})$  (5),<sup>6,7</sup>  $\text{Cp}'\text{W}(\text{CO})_3(\text{X})$  (X = H, halide, alkyl) (6),<sup>8</sup> and  $[\text{Cp}'\text{W}(\text{CO})_3]_2$  (7).<sup>9</sup> Seven-coordinate halocarbonyl complexes of the type  $\text{W}(\text{CO})_{5-n}(\text{L})_n(\text{X})_2$  ( $n = 1, 2$ ; X = halide) are obtained upon addition of L to  $[\text{W}(\text{CO})_4(\text{X})(\mu\text{-X})_2]$  or from the reactions of halogens with  $\text{W}(\text{CO})_{6-n}(\text{L})_n$ .<sup>10,11</sup>

The Lewis-acidic (see *Lewis Acids & Bases*)  $\text{W}(\text{CO})_5$  fragment binds a variety of weakly coordinating ligands. As a result, there are a great many  $\text{W}(\text{CO})_5(\text{L})$  complexes known, some of which have found applications in catalysis (see *Organic Synthesis using Transition Metal Carbonyl Complexes*). For example, the thirane complex  $\text{W}(\text{CO})_5(\text{SCH}_2\text{CH}_2)$  catalyzes the conversion of thioethers to cyclic disulfides.<sup>12</sup> Of particular interest are transient  $\text{W}(\text{CO})_5(\text{alkane})$  complexes detected by IR spectroscopy at low temperature upon irradiation of  $\text{W}(\text{CO})_6$  in hydrocarbon solvents; in these  $\sigma$ -alkane adducts, the tungsten atom interacts with a single C–H bond of the alkane ligand.<sup>13</sup> The  $\text{W}(\text{CO})_5(\text{alkane})$  derivatives react rapidly with Lewis bases (see *Lewis Acids & Bases*) to form  $\text{W}(\text{CO})_5(\text{L})$ , which may also be generated directly by photolysis of  $\text{W}(\text{CO})_6$  in the presence of L. In related  $\text{W}(\text{CO})_5(\eta^1\text{-BH}_3\cdot\text{L})$  complexes (L = py, NMe<sub>3</sub>, PMe<sub>3</sub>), the borane-Lewis base adduct coordinates with the tungsten center via a B–H bond in a three-center, 2e interaction (see *Dihydrogen Complexes & Related Sigma Complexes*).<sup>14</sup>

The most common mode of reactivity involving carbonyl ligands in organometallic complexes of tungsten is CO insertion into a W–R bond (R = alkyl, aryl) to form tungsten-acyl complexes. For example, the reaction of *cis*- $\text{Cp}^*\text{W}(\text{CO})_2(\text{MeCN})(\text{Me})$  with CNBu<sup>t</sup> affords a mixture of ligand-substitution products, *cis*- and *trans*- $\text{Cp}^*\text{W}(\text{CO})_2(\text{CNBu}^t)(\text{Me})$ , and the CO insertion products, *cis*- and *trans*- $\text{Cp}^*\text{W}(\text{CO})(\text{CNBu}^t)_2(\text{COMe})$ .<sup>15</sup> A remarkable 6e reductive cleavage of a CO ligand occurs upon thermolysis of  $[\text{WCl}(\text{CO})(\text{OR})_2]_2$  (8, R = SiBu<sup>t</sup><sub>3</sub>) at 120 °C in toluene to give the oxo- $\mu$ -carbido complex  $(\text{RO})_2(\text{O})\text{W}=\text{C}=\text{WCl}_2(\text{OR})_2$  (9) (equation 3). An analogous

imido- $\mu$ -carbido complex  $(\text{RO})_2(\text{ArN})\text{W}=\text{C}=\text{WCl}_2(\text{OR})_2$  is formed when the related aryl isocyanide species,  $(\text{RO})_4\text{W}_2\text{Cl}_2(\text{CNAr})$  (Ar = 2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>), is heated at 60 °C in the same solvent.<sup>16</sup>

## 2.2 Tungsten–Isocyanide and –Cyanide Complexes

Neutral and cationic homoleptic (see *Homoleptic Compound*) tungsten–isocyanide complexes  $\text{W}(\text{CNR})_6$  and  $[\text{W}(\text{CNR})_7]^{2+}$  (R = alkyl, aryl) are known,<sup>17</sup> and  $\text{W}(\text{CO})_{6-n}(\text{CNR})_n$  ( $n = 1\text{--}3$ ) complexes may be prepared from  $\text{W}(\text{CO})_6$  and excess isocyanide in the presence of catalytic amounts of CoCl<sub>2</sub> or PdO.<sup>18,19</sup> Isocyanides are isoelectronic with CO and also insert into the W–R bonds of alkyl complexes (see *Alkyl Complexes*). For instance, the alkyl–nitrosyl complexes  $\text{Cp}^*\text{W}(\text{NO})(\text{X})(\text{CH}_2\text{Bu}^t)$  (X = NHBu<sup>t</sup>, OBu<sup>t</sup>) react with CNBu<sup>t</sup> to afford  $\eta^2$ -iminoacyl complexes,<sup>20</sup> and the isocyanide complexes,  $\text{Cp}^*\text{W}(\text{CO})_2(\text{Me})(\text{CNR})$  (10, R = alkyl), rearrange to afford either  $\eta^2$ -iminoacyl  $\text{Cp}^*\text{W}(\text{CO})_2(\eta^2\text{-MeCNR})$  (11) or  $\eta^3$ -1-azaallyl  $\text{Cp}^*\text{W}(\text{CO})_2(\eta^3\text{-CH}_2\text{CHNR})$  (12) derivatives, depending upon the reaction conditions (equation 4).<sup>21</sup>

The coupling of isocyanide ligands (see *Isocyanide Ligands*) via C–C bond formation has also been observed. Thus,  $[(\text{Me}_3\text{SiN})_2\text{C}_6\text{H}_4](\text{NPh})\text{WMe}_2$  reacts with CNBu<sup>t</sup> to form the octahedral adduct  $[(\text{Me}_3\text{SiN})_2\text{C}_6\text{H}_4](\text{NPh})\text{WMe}_2(\text{CNBu}^t)$  (13), which in the presence of CNBu<sup>t</sup> is converted to a trigonal–bipyramidal bis( $\eta^2$ -iminoacyl) species (14) that

thermally isomerizes to the square-pyramidal metallacyclic complex (15) (equation 5,  $R = \text{SiMe}_3$ ).<sup>22</sup>

Research involving the octacyanotungstate anions,  $[\text{W}(\text{CN})_8]^{n-}$  ( $n = 3, 4$ ), is experiencing a renaissance since these complexes exhibit unusual photochemical behavior and have been used as molecular components for the construction of multidimensional polymeric materials;<sup>23,24</sup> for instance, the reaction of  $\text{K}_4[\text{W}(\text{CN})_8]$  with  $\text{Me}_3\text{SnCl}$  affords the three-dimensional coordination polymer  $\{(\text{Me}_3\text{Sn})_4[\text{W}(\text{CN})_8]\}_n$ .<sup>25</sup> The octacyanotungstate anions may possess dodecahedral or square-antiprismatic coordination geometries in the solid state (see *Cyanide Complexes of the Transition Metals*), and the addition of labile (see *Labile*) coordination complexes to solutions of  $[\text{W}(\text{CN})_8]^{n-}$  often affords compounds that possess potentially useful magnetic properties. Specifically, the reaction of  $[\text{HNBu}_3][\text{W}(\text{CN})_8]$  with  $\text{Mn}(\text{ClO}_4)_2$  in EtOH provides  $\text{Mn}_9[\text{W}(\text{CN})_8]_6 \cdot 24\text{EtOH}$  that consists of cyanide-bridged  $\text{Mn}^{\text{II}}_9\text{W}^{\text{V}}_6$  units with a capped-cubane geometry and exhibits the largest known spin-value  $S = 39/2$  ground state.<sup>26</sup>

### 3 TUNGSTEN COMPLEXES CONTAINING HYDROCARBON LIGANDS

#### 3.1 $\eta^1$ -Hydrocarbyl Complexes

##### 3.1.1 Alkyl and Aryl Complexes

Hexamethyltungsten,  $\text{WMe}_6$  (16), was first isolated by Wilkinson and coworkers, and it may be prepared by the reactions of  $\text{WCl}_6$  with methylating reagents such as  $\text{MeLi}$ ,  $\text{AlMe}_3$ ,

Scheme 1

or  $\text{ZnMe}_2$ . Recent structural analyses have shown that (16) has a distorted trigonal-prismatic structure of  $C_{3v}$  symmetry with three long and three short W–C bonds,<sup>27</sup> an unusual structural motif found primarily in  $d^0$  (see *d<sup>n</sup> Configuration*) complexes containing  $\sigma$ -only donor ligands.<sup>28</sup> The reactions of (16) with  $\text{O}_2$  or  $\text{MeOH}$  afford  $\text{W}(\text{OMe})_6$  (17), and treatment with  $\text{CO}$  forms  $\text{W}(\text{CO})_6$  and  $\text{Me}_2\text{CO}$ .<sup>29</sup> In contrast, the reaction of (16) with  $\text{NO}$  affords  $\text{WMe}_4(\text{MeN}_2\text{O}_2)_2$  (18),<sup>30</sup> and the seven- and eight-coordinate alkyl anions  $[\text{WMe}_7]^-$  (19),  $[\text{WMe}_6(\text{CH}_2\text{SiMe}_3)]^-$ , or  $[\text{WMe}_8]^{2-}$  are formed when (16) is treated with  $\text{RLi}$  ( $R = \text{Me}, \text{CH}_2\text{SiMe}_3$ ) reagents (Scheme 1).<sup>31,32</sup> Photolysis of (16) in the presence of  $\text{PMe}_3$  produces  $\text{W}(\text{Me})(\equiv\text{CMe})(\text{PMe}_3)_4$  (20) and  $\text{CH}_4$ ,<sup>33</sup> and an unusual five-coordinate  $\text{W}^{\text{VI}}$  imido complex (21) is formed when (16) is treated with excess  $\text{CNBu}^t$ .<sup>29</sup> Mixed complexes  $\text{WX}_n\text{Me}_{6-n}$  are predicted to exhibit a gradual increase in the preference for octahedral geometry as  $n$  increases;<sup>34</sup> for instance,  $\text{WMe}_5\text{X}$  ( $X = \text{Cl}, \text{F}$ ) species possess a distorted trigonal-prismatic geometry, while  $\text{WMe}_3(\text{OMe})_2\text{Cl}$  and  $\text{WF}_6$  are octahedral molecules.<sup>35</sup> Few other homoleptic (see *Homoleptic Compound*) alkyl complexes of tungsten are known, but  $\text{W}(\text{CH}_2\text{Ph})_4$ ,<sup>36</sup> along with ditungsten complexes  $\text{W}_2(\text{CH}_2\text{R})_6$  ( $R = \text{Ph}, \text{SiMe}_2\text{Ph}$ ) containing a  $\text{W}\equiv\text{W}$

triple bond<sup>37</sup> have been reported. Homoleptic (*see Homoleptic Compound*) aryl complexes  $W(\text{aryl})_4$  (aryl = 2-MeC<sub>6</sub>H<sub>4</sub> (**22**), 2,5-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) may be prepared by treating  $W(\text{OPh})_6$  with appropriate Grignard reagents (*see Grignard Reagents*), and they react with  $\text{PMe}_3$  to give the  $\eta^2$ -aryne complexes  $W(\eta^2\text{-C}_6\text{H}_3\text{MeR})(\text{aryl})_2(\text{PMe}_3)_2$  (R = H (**23**), Me) (equation 6).<sup>38</sup>

In general, alkyl and aryl complexes of tungsten are prepared by metathesis of suitable halide precursors using various alkylating or arylating reagents. Thus,  $\text{Tp}^*\text{W}(\text{O})_2\text{R}$  derivatives (R = Me,  $\text{CH}_2\text{SiMe}_3$ ,  $\text{CH}_2\text{Bu}^t$ ,  $\text{CH}_2\text{CMePh}_2$ , etc.) are obtained from  $\text{Tp}^*\text{W}(\text{O})_2\text{Cl}$  and Grignard reagents (*see Grignard Reagents*),<sup>39</sup> and the 16e dialkyl-nitrosyl complexes  $\text{Cp}^*\text{W}(\text{NO})\text{R}_2$  are accessed by treating  $[\text{Cp}'\text{W}(\text{NO})\text{Cl}_2]_n$  ( $\text{Cp}' = \text{Cp}$ ,  $\text{Cp}^*$ ;  $n = 1, 2$ ) with dialkylmagnesium reagents,  $\text{R}_2\text{Mg} \cdot x(\text{dioxane})$ .<sup>40</sup> For instance, the reaction of  $\text{Cp}^*\text{W}(\text{NO})\text{Cl}_2$  with MeLi affords the monomeric dimethyl complex,  $\text{Cp}^*\text{W}(\text{NO})\text{Me}_2$ , which reacts with  $\text{PMe}_3$  to form an isolable  $\text{Cp}^*\text{W}(\text{NO})\text{Me}_2(\text{PMe}_3)$  adduct. In the absence of a supporting donor interaction, the dimethyl compound undergoes spontaneous isomerization via nitrosyl N–O bond cleavage to its oxo(imido) form,  $\text{Cp}^*\text{W}(\text{NMe})(\text{O})\text{Me}$ .<sup>41</sup>

Electron-deficient tungsten-alkyl complexes exhibit some unusual bonding interactions. Specifically, the benzyl complexes  $\text{Cp}^*\text{W}(\text{NO})(\eta^2\text{-CH}_2\text{Ph})(\text{R})$  possess W- $\eta^2$ -benzyl linkages,<sup>42</sup> and the bis(neopentyl) compound,  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{Bu}^t)_2$  (**24**), contains one strongly agostic and one weakly agostic methylene hydrogen atom in the solid state, and these  $\alpha$ -agostic (*see Agostic Bonding*) interactions persist in solutions.<sup>43</sup> In addition, these alkyl complexes undergo thermal or photochemical reactions to give alkene (*see Alkene Complexes*), alkylidene (*see Alkylidene*), or alkylidyne (*see Alkylidyne*) complexes that are discussed further in the appropriate sections (*vide infra*). Thermolysis of (**24**) in methyl-substituted arenes such as *p*-xylene results in the  $\alpha$ -elimination (*see  $\alpha$ -Elimination*) of neopentane and formation of a mixture containing the aryl and the  $\eta^2$ -benzyl complexes, that is,  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{Bu}^t)(2,5\text{-Me}_2\text{C}_6\text{H}_3)$  (**25**) and  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{Bu}^t)(\eta^2\text{-CH}_2\text{C}_6\text{H}_4\text{-4-Me})$  (**26**), derived from aromatic  $\text{sp}^2$  or benzylic  $\text{sp}^3$  C–H bond activations of the solvent molecule, respectively (equation 7) (*see Alkane Carbon–Hydrogen Bond Activation*). These and related mixed alkyl-aryl species may also be produced by metatheses

from  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{Bu}^t)(\text{Cl})$  and appropriate aryl Grignard reagents (*see Grignard Reagents*).

Treatment of  $\text{Cp}^*\text{W}(\text{NO})\text{Cl}_2$  with  $(\text{aryl})_2\text{Mg}$  (aryl = Ph, *o*- and *p*-tolyl) affords 16e  $\text{Cp}^*\text{W}(\text{NO})(\text{aryl})_2$  complexes that react with CO, CO<sub>2</sub>, CS<sub>2</sub>, or aryl isocyanates to produce  $\eta^2$ -acyl,  $\eta^2$ -carboxylate,  $\eta^2$ -thiocarboxylate, and  $\eta^2$ -amide-containing complexes, respectively.<sup>40,44</sup> In a related system, the water-induced isomerization of  $\text{CpW}(\text{NO})(o\text{-tolyl})_2$  affords the isomeric oxo(imido) complex  $\text{CpW}(\text{O})(\text{N-}o\text{-tolyl})(o\text{-tolyl})$ .<sup>45</sup> Furthermore, the ortho-metalated phosphine complex,  $\text{Cp}^*\text{W}(\text{NO})(\text{H})(\eta^2\text{-PPh}_2\text{C}_6\text{H}_4)$  (**27**), undergoes intramolecular reductive elimination (*see Reductive Elimination*) of the aryl and hydrido ligands to afford the strong  $\pi$ -donor fragment  $\text{Cp}^*\text{W}(\text{NO})(\text{PPh}_3)$ , which subsequently reacts with unsaturated molecules  $\text{L} = \text{CNR}$  (R =  $\text{Bu}^t$ , Cy),  $\text{Me}_2\text{CO}$ , and EtOAc to afford  $\text{Cp}^*\text{W}(\text{NO})(\text{PPh}_3)(\eta^2\text{-L})$  adducts, including the  $\eta^2$ -ester complex (**28**, equation 8).<sup>46</sup>

### 3.1.2 Vinyl and Alkynyl Complexes

Vinyl (or alkenyl) ligands may adopt either  $\eta^1$ - (**A**) or  $\eta^2$ - (**B**) limiting coordination modes depending on the electronic saturation of the tungsten center. In  $\eta^2$ -vinyl complexes, both alkenyl carbon atoms are bound to the metal, and the resulting metallacyclopropene ligand increases the formal electron

count at the metal by two relative to an  $\eta^1$ -vinyl ligand.<sup>47</sup> Typical synthetic routes to vinyl complexes involve transmetallation using vinylmagnesium reagents, deprotonation of  $\eta^2$ -alkene ligands, and nucleophilic addition (e.g. protonation) of  $\eta^2$ -alkyne ligands. The insertion of an alkyne into a W–H bond also affords a vinyl complex, as in the reaction of  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{SiMe}_3)(\text{H})$  with  $\text{PhC}\equiv\text{CH}$  to form  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{SiMe}_3)(\eta^2\text{-CPh=CH}_2)$ .<sup>48</sup>  $\eta^1$ -Vinyl complexes can isomerize via a formal [1,2]-H shift to generate alkylidyne complexes; these reactions generally proceed via formation of intermediate metallacyclopropene species (**B**) and therefore require a vacant coordination site at the tungsten center. The isomerization of  $\eta^2$ -vinyl complexes to  $\eta^3$ -allyl complexes via intermediate  $\eta^2$ -allene hydride species has also been documented.<sup>47</sup>

Deprotonation of  $\text{Tp}^*\text{W}(\text{CO})_2(\eta^2\text{-H}_2\text{C=C}(\text{CH}_2\text{R}))$  ( $\text{R} = \text{H, Pr, Ph}$ ) at the  $\beta'$ -site results in the formation of anionic  $\eta^2$ -allene species  $[\text{Tp}^*\text{W}(\text{CO})_2(\eta^2\text{-H}_2\text{C=C=CHR})]^-$ , which react in turn with  $\text{MeI}$  to form  $\text{Tp}^*\text{W}(\text{CO})_2(\eta^2\text{-H}_2\text{C=C}(\text{CHRMe}))$ .<sup>49</sup> Furthermore, the characteristic chemistry of dioxotungsten–vinyl complexes has been described,<sup>50</sup> and sequential C–F oxidative addition (see *Oxidative Addition*) and migratory insertion of electron-deficient alkynes at a tungsten center gives rise to novel  $\eta^2$ -vinyl complexes (**29**) in which an aromatic C–F bond has been replaced by a C–C bond (equation 9).<sup>51</sup>

The solid-state molecular structure of  $\text{Cp}^*\text{W}(\text{NO})(\text{CH}_2\text{SiMe}_3)(\text{CPh=CH}_2)$  (**30**) reveals that its vinyl ligand exists in a distorted form that cannot readily be described by either of the classic  $\eta^1$ -vinyl (**A**) or 1-metallacyclopropene (**B**) limiting structures. However, the NMR spectroscopic parameters for the  $\text{CPhCH}_2$  fragment of (**30**) in solutions are characteristic of those of structure **B**, a feature reflecting the metal center's attainment of the favored 18e configuration (see *Eighteen Electron Compounds*). Thermolysis of (**30**) in neat hydrocarbon solutions transiently generates  $\text{Cp}^*\text{W}(\text{NO})(\eta^2\text{-PhC}\equiv\text{CH})$ , which subsequently activates solvent C–H bonds to afford either 18e  $\text{Cp}^*\text{W}(\text{NO})(\text{R})(\eta^2\text{-CPh=CH}_2)$  complexes (e.g.  $\text{R} = \text{phenyl}$ ) or 18e  $\eta^1, \eta^3$ -metallacyclic species (**31**) ( $\text{R} = \text{OEt, Pr}^n, \text{Bu}^n, \text{Bu}^t$ ) (see *Alkane Carbon–Hydrogen Bond Activation*). In the absence of alkyl groups with  $\beta$ -C–H bonds, a different mode of reactivity occurs; for instance, the activation of 2,3-dimethyl-2-butene results in fusion of the olefinic fragment to the vinyl ligand at the  $\alpha$ -C of the vinyl moiety, and two C–H bond activations occur at the trans- $\gamma$  positions of the olefinic substrate to afford (**32**).

Alkynyl complexes are typically prepared by the reactions of appropriate tungsten precursors with acetylide reagents, for example  $\text{LiC}\equiv\text{CR}$ , or by deprotonation of  $\eta^2$ -alkyne or vinylidene complexes. The characteristic reactivity of alkynyl complexes most commonly involves electrophilic attack at the  $\beta$ -carbon, a fact rationalized by invoking resonance forms **C** and **D** shown below. Form **D** becomes dominant as the electron density on the complex increases, and therefore anionic complexes of the type  $[\text{W}(\text{CO})_5(\text{C}\equiv\text{CR})]^-$ ,  $[\text{W}(\text{CO})_4(\text{PPh}_3)(\text{C}\equiv\text{CR})]^-$  or *fac*- $[\text{W}(\text{C}\equiv\text{CR})(\text{CO})_3(\text{dppe})]^-$  react with electrophiles exclusively at the  $\beta$ -carbon atom to yield vinylidene complexes.<sup>52,53</sup> Likewise, the negative charge in  $[\text{CpW}(\text{CO})_2]_2(\mu\text{-}\sigma\text{:C}\equiv\text{CPh})^-$  is delocalized between the tungsten atom and the  $\beta$ -carbon atom of the bridging alkynyl ligand.<sup>54</sup> Neutral  $\text{W}(\text{CO})_2(\text{NO})(\text{dppe})(\text{C}\equiv\text{CR})$  ( $\text{R} = \text{H, Bu}^t, \text{Pr}^n$ ) compounds have also been described, but these nitrosyl complexes (see *Nitrosyl Complexes*) do not react with electrophiles to afford vinylidene complexes.<sup>55</sup>

In rare cases, electrophilic attack may occur directly at the metal center of an alkynyl complex, as when anionic  $[\text{CpW}(\text{NO})(\text{CO})(\text{C}\equiv\text{CR})]^-$  ( $\text{R} = \text{SiMe}_3$ ,  $\text{Bu}^t$ ,  $\text{Ph}$ ) is treated with allylic iodides to obtain  $\text{CpW}(\text{NO})(\eta^3\text{-allyl})(\text{C}\equiv\text{CR})$  via a sequence involving electrophilic attack at the tungsten, CO elimination, and  $\eta^1 \rightarrow \eta^3$  isomerization of the allyl ligand.<sup>56</sup> Isolable *trans*- $\text{W}(\text{C}\equiv\text{CR})(\text{CO})_2(\eta^3\text{-allyl})(\text{dmpm})$  complexes (**33**) are prepared from *cis*- $\text{WCl}(\text{CO})_2(\eta^3\text{-allyl})(\text{dmpm})$  and  $\text{LiC}\equiv\text{CR}$ , and the alkynyl ligand of (**33**) can undergo an intramolecular (*see Intramolecular*) metal-to-allyl migration to produce free enynes derived from alkynyl–allyl coupling (equation 10).<sup>57</sup>

Photolysis of *trans*- $\text{W}(\text{N}_2)_2(\text{dppe})_2$  in the presence of  $\text{RC}\equiv\text{CH}$  ( $\text{R} = \text{Ph}$ ,  $\text{CO}_2\text{Me}$ ,  $\text{CO}_2\text{Et}$ ) gives a mixture of the alkynyl complexes, *trans*- $[\text{M}(\text{C}\equiv\text{CR})_2(\text{dppe})_2]$ , and eight-coordinate *trans*- $[\text{W}(\text{H})_2(\text{C}\equiv\text{CR})_2(\text{dppe})_2]$ . The latter compounds react with  $\text{HBF}_4$  to give either neutral  $\text{WF}(\equiv\text{CCH}_2\text{R})(\text{dppe})_2$  ( $\text{R} = \text{CO}_2\text{Me}$ ) or cationic  $[\text{WF}(\equiv\text{CHCH}_2\text{R})(\text{dppe})_2]^+$  ( $\text{R} = \text{Ph}$ ).<sup>58</sup> Reactions of  $\text{LiC}\equiv\text{CR}$  with  $\text{W}_2\text{Cl}_4(\text{PMe}_3)_4$  afford  $\text{W}_2(\text{C}\equiv\text{CR})_4(\text{PMe}_3)_4$  complexes of  $D_{2d}$  symmetry; however, the alkynyl ligands in these complexes are not oriented parallel to one another due to a combination of steric and electronic effects. The existence of  $\pi$ - $\delta$ - $\pi$  conjugation (involving the  $\pi/\pi^*$  and  $\delta/\delta^*$  orbitals of the alkynyl and metal–metal quadruple bond, respectively) in these and related complexes has been demonstrated using a variety of spectroscopic techniques, and the IR  $\nu(\text{C}\equiv\text{C})$  frequencies have been shown to be a sensitive probe of orbital mixing.<sup>59</sup> Finally, the unusual methylidyne complexes,  $\text{W}(\text{C}\equiv\text{CR})(\equiv\text{CH})(\text{dmpe})_2$  ( $\text{R} = \text{H}$ ,  $\text{Ph}$ ,  $\text{SiMe}_3$ ), contain linear metallabutadiyne units that exhibit considerable  $\pi$ - $\text{HC}\equiv\text{W}-\text{C}\equiv\text{CR}$  conjugation.<sup>60</sup>

The alkynyl complexes  $\text{CpW}(\text{CO})_3(\text{C}\equiv\text{CR})$  are versatile reagents for the preparation of organometallic cluster compounds<sup>61</sup> (*see Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements*), and they and propargyl complexes of the type  $\text{CpW}(\text{CO})_3(\text{CH}_2\text{C}\equiv\text{CR})$  (**34**) have found use as templates during the synthesis of heterocyclic and carbocyclic compounds, especially lactones (e.g. equation 11).<sup>62</sup> Treatment of  $\text{CpW}(\text{CO})_3(\text{CH}_2\text{C}\equiv\text{CH})$  with  $[\text{Ph}_3\text{C}]\text{PF}_6$  generates cationic  $[\text{CpW}(\text{CO})_3(\eta^2\text{-H}_2\text{C}=\text{C}=\text{CHCPh}_3)]^+$ , which

eliminates trityllallene,  $\text{H}_2\text{C}=\text{C}=\text{CHCPh}_3$ , upon treatment with excess  $\text{Me}_3\text{NO}$ .<sup>63</sup> The reaction of  $\text{CpW}(\text{CO})_3\text{Cl}$  with buta-1,3-diyne in the presence of  $\text{CuI}/\text{NHET}_2$  affords  $\text{CpW}(\text{CO})_3(\text{C}\equiv\text{CC}\equiv\text{CH})$ , from which a series of functionalized diyne derivatives  $\text{CpW}(\text{CO})_3(\text{C}\equiv\text{CC}\equiv\text{CR})$  ( $\text{R} = \text{Ph}$ ,  $\text{SiMe}_3$ ,  $\text{P}(\text{O})\text{Ph}_2$ ) may be obtained.<sup>64</sup> Furthermore, the alkynyl ligand in  $\text{Cp}^*\text{W}(\text{CO})(\text{C}\equiv\text{CR})(\eta^2\text{-HC}\equiv\text{CR})$  reacts with  $[\text{Me}_3\text{O}]\text{BF}_4$  to form the cationic vinylidene complex (**35**) that when deprotonated in the presence of CO affords the coupled product  $\text{Cp}^*\text{W}(\text{CO})_2(\eta^3\text{-RC}\equiv\text{CC}=\text{CMeR})$  (**36**,  $\text{R} = \text{Bu}^t$ , equation 12).<sup>65</sup>

Finally, the reaction of  $[\text{CpW}(\text{CO})_3]^-$  with  $\text{CH}_2\text{I}_2$  in MeCN produces the dinuclear acetylide complex  $[\text{CpW}(\text{CO})_3]_2(\mu\text{-C}\equiv\text{C})$  (**37**) along with  $\text{CpW}(\text{CO})_3\text{Me}$  and  $\text{CpW}(\text{CO})_3\text{I}$ , but when the same reaction is carried out in MeOH, the dinuclear ketene complex  $\text{Cp}_2\text{W}_2(\text{CO})_5(\mu, \eta^1, \eta^2\text{-CH}_2\text{CO})$  (**38**) is obtained.<sup>66</sup>

### 3.1.3 Carbene Complexes

Tungsten–carbene complexes contain  $\text{W}=\text{C}$  linkages, and if they also contain alkyl substituents on the carbene carbon,

they are frequently referred to as alkylidene complexes (see **Carbene Complexes**). The two extreme types of carbene complexes are the Schrock type (39) with at least one alkyl substituent on the  $\alpha$ -carbon atom, and the Fischer type (40), which possess a  $\pi$ -donor heteroatom substituent on the  $\alpha$ -carbon atom. However, many carbene complexes lie between these extremes. Fischer carbenes (see *Fischer-type Carbene Complexes*) contain the metal in a low oxidation state and have  $\pi$ -donor substituents on  $C_\alpha$ , which exhibits electrophilic behavior that is generally ascribed to the combined effect of  $\pi$ -acceptor ligands on the metal and inductive effects of the electronegative heteroatom substituent.

The first tungsten–carbene complexes were generated by Fischer in 1964 by the addition of alkyllithium reagents to  $W(CO)_6$  followed by quenching with an electrophile (see *Electrophile*). Derivatives of these species exhibit a multitude of carbene-centered ligand reactions and interligand coupling reactions,<sup>67,68</sup> and they have been used for the polymerization of alkynes and as a carbene source for the cyclopropanation of alkenes. Related (1-alkynyl)carbene complexes (41) have found use in various cyclization reactions,<sup>69</sup> and 1-metalla-1,3,5-hexatriene complexes are key intermediates during the synthesis of heterocyclic compounds (e.g. equation 13); they have also been used as stoichiometric reagents in organic synthesis.<sup>70</sup> Related allenylidene complexes  $W(CO)_5(=C=C=CR_2)$  react with amines, imines, and hydrazines via addition of the nitrogen nucleophile (see *Nucleophile*) to the  $C_\alpha$  allenylidene atom.<sup>71</sup> Interestingly, the reaction of  $W(CO)_5(=CHPh)$  with  $RC\equiv CR$  affords both the dinuclear complex (42) and the alkyne insertion product (43,  $R = NMe_2$ ).<sup>72</sup>

In Schrock-type carbene complexes (see *Schrock-type Carbene Complexes*), the tungsten is typically in a high oxidation state and the  $C_\alpha$  substituents are devoid of  $\pi$ -donor character, and the resulting strong  $W \rightarrow C_\alpha \pi$ -backbonding interaction (see *Back Bonding*) imparts nucleophilic behavior on the complexes. The alkylidene ligands in these complexes are most commonly formed by  $\alpha$ -deprotonation of an alkyl group. Such transformations may occur upon coordinative saturation of the metal center, as in the reaction of  $W(\equiv C Bu')(CH_2 Bu')_3$  (44) with  $PMe_3$  to afford  $W(\equiv C Bu')(=CH Bu')(CH_2 Bu')(PMe_3)_2$  (45) (equation 14,  $R = Bu'$ ),<sup>73</sup> or during intramolecular  $\alpha$ -H elimination (see  *$\alpha$ -Elimination*) reactions induced by thermal or photochemical means. Finally, it should be noted that tungsten–carbene complexes may be prepared by direct carbene transfer, as in the synthesis of  $W(=CHR)Cl_2(NPh)(PMePh_2)_2$  from the reactions of  $WCl_2(NPh)(PMePh_2)_3$  and  $Ph_3P=CHR$  ( $R = \text{aryl, vinyl}$ ).<sup>74</sup>

Thermolysis of  $Cp^*W(NO)(CH_2 Bu')_2$  in neat hydrocarbon solutions transiently generates the neopentylidene complex,  $Cp^*W(NO)(=CH Bu')$ , which subsequently activates solvent C–H bonds.<sup>75</sup> The trialkyl complexes  $Cp^*W(NBu')(CH_2 R)_3$  ( $R = Me, Et$ ) undergo a similar thermal decomposition to afford the isolable alkylidene derivatives,  $Cp^*W(NBu')(=CHR)(CH_2 R)$ .<sup>76</sup> Photolysis of the metallacyclopentane complex,  $\{p\text{-}Bu'\text{-calix[4]-(O)}_4\}W(CH_2)_4$  (46), affords the alkylidene complex,  $\{p\text{-}Bu'\text{-calix[4]-(O)}_4\}W(=CHPr)$  (47, equation 15).<sup>77</sup> The related  $W^{VI}$  alkylidene complex,  $(NPh)W(=CHSiMe_3)(CH_2 SiMe_3)(OR)$  ( $R = C(py)Ph_2$ ), is formed via intramolecular  $\alpha$ -H abstraction from the trialkyl complex  $(NPh)W(CH_2 SiMe_3)_3(OR)$ ,<sup>78</sup> and the unusual square–pyramidal compound,  $[(Me_3 SiN)_2 C_6 H_4](NPh)W(=CH Bu')(PMe_3)_2$ , reacts with ethene to afford the metallacyclopentane complex,  $[(Me_3 SiN)_2 C_6 H_4](NPh)W(CH_2)_4$

and neohexene.<sup>79</sup>

Protonation of the  $\eta^2$ -vinyl complex,  $\text{Tp}^*\text{W}(\text{CO})_2(\eta^2\text{-CPh=CHMe})$ , with  $\text{HBF}_4$  affords the cationic alkylidene complex,  $[\text{Tp}^*\text{W}(\text{CO})_2(=\text{CPhCH}_2\text{Me})]^+$ ,<sup>47</sup> and this and related  $\text{Tp}^*\text{W}(\text{CO})_2(=\text{CMePh})$  complexes contain  $\beta$ -agostic (see *Agostic Bonding*) C–H bonds.<sup>80</sup> In a similar manner, protonation of  $\text{W}(\equiv\text{CR})(\text{Cl})(\text{CO})(\text{L})(\text{PMe}_3)_2$  ( $\text{L} = \text{PMe}_3$ ,  $\text{py}$ ) with  $\text{HCl}$  affords an alkylidene complex,  $\text{W}(=\text{CHR})(\text{Cl})_2(\text{CO})(\text{PMe}_3)_2$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ ,  $\text{Ph}$ ,  $p\text{-Tol}$ ), that contains  $\alpha$ -agostic C–H interactions.<sup>81</sup> The related  $\eta^3$ -allylidene complex  $\text{W}(=\text{CPhCH=CHMe})(\text{Br})_2(\text{CO})_2(\text{L})$  (**48**) contains an alkylidene ligand that coordinates with the metal via a second intraligand donor site involving the  $\beta$ - and  $\gamma$ -carbon atoms.<sup>82</sup> Alternatively, the deprotonation of  $\text{Tp}^*\text{W}(\text{CO})(\text{Me})(\eta^2\text{-PhC}\equiv\text{CMe})$  with trityl cation yields the cationic methylene complex  $[\text{Tp}^*\text{W}(\text{CO})(=\text{CH}_2)(\eta^2\text{-PhC}\equiv\text{CMe})]^+$ .<sup>83</sup> Finally, treatment of the anionic alkylidene complex,  $[\text{CpW}(\text{CO})_2(=\text{CHPh})]^-$ , with  $\text{MeI}$  affords *trans*- $\text{CpW}(\text{Me})(\text{CO})_2(=\text{CHPh})$  that isomerizes via an intramolecular (see *Intramolecular*) methyl-to-carbene migration to form the  $\eta^3$ -benzyl complex,  $\text{CpW}(\text{CO})_2(\eta^3\text{-CH(Me)C}_6\text{H}_5)$  (**49**).<sup>84</sup>

Complexes incorporating a  $\text{W}^{\text{VI}}$  center with supporting alkoxide ligands and an imido ligand, for example

$\text{W}(\text{NAr})(=\text{CHBu}^t)(\text{OR})_2$  ( $\text{R} = \text{CMe}(\text{CF}_3)_2$ , **50**) are highly active catalysts for the metathesis of internal alkenes (equation 16),<sup>85</sup> and also effect the stereoselective olefination of hydroxy ketones (equation 17).<sup>86</sup> The reactivity of these catalysts can be tuned by varying the alkoxide ligands; for example, when  $\text{R} = \text{Bu}^t$ , the complex acts only upon strained cyclic alkenes and is a highly effective ring-opening metathesis polymerization (ROMP) catalyst (see *Metathesis Polymerization Processes by Homogeneous Catalysis*).

### 3.1.4 Carbyne Complexes

Tungsten–carbyne (or alkylidyne) complexes (see *Carbyne Complexes*) contain  $\text{W}\equiv\text{C-R}$  linkages that are often slightly bent. This bending has been attributed to electronic rather than steric effects,<sup>87</sup> and spectroscopic investigations have revealed carbon p orbital character in these bonds greater than that expected for formal  $\text{sp}$ -hybridization.<sup>88</sup> The first tungsten–carbyne complexes, *trans*- $\text{W}(\text{CO})_4(\equiv\text{CR})(\text{X})$  ( $\text{R} = \text{alkyl}$ ,  $\text{X} = \text{halide}$ ), were obtained by Fischer who treated his carbene complexes with  $\text{BX}_3$ . Using related methodology, alkynylcarbyne complexes  $\text{W}(\text{CO})_2(\equiv\text{CC}\equiv\text{CR})(\text{CF}_3\text{CO}_2)(\text{bipy})$  ( $\text{R} = \text{SiMe}_3$ ,  $\text{Ph}$ ,  $p\text{-Tol}$ ,  $\text{Bu}^t$ ) may be prepared by treating  $\text{W}(\text{CO})_6$  with  $\text{LiC}\equiv\text{CR}$ , trifluoroacetic anhydride, and bipy in a sequential manner.<sup>89</sup>

High-valent alkylidyne complexes (see *Schrock-type Carbyne Complexes*) of tungsten are most commonly prepared from alkylidene precursors by  $\alpha$ -deprotonation or  $\alpha$ -H elimination (see  *$\alpha$ -Elimination*). These reactions are often facile, as illustrated by the reaction of  $\text{WCl}_6$  with  $\text{LiCH}_2\text{Bu}^t$  to give dimeric  $[\text{W}(\text{CH}_2\text{Bu}^t)_3(\mu\text{-CBu}^t)]_2$  with bridging neopentylidyne ligands. This dimeric compound readily dissociates into monomers that react with  $\text{PMe}_3$  to produce neopentane and  $\text{W}(\text{CH}_2\text{Bu}^t)(=\text{CHBu}^t)(\equiv\text{CBu}^t)(\text{PMe}_3)_2$ .<sup>73</sup> In a related manner, treatment of  $\text{W}(\equiv\text{CBu}^t)(\text{CH}_2\text{Bu}^t)_2\text{Cl}$  with  $\text{Li}(\text{THF})_3\text{SiPh}_2\text{Bu}^t$  affords an equilibrium mixture of  $\text{W}(\equiv\text{CBu}^t)(\text{CH}_2\text{Bu}^t)_2(\text{SiPh}_2\text{Bu}^t)$  (**51**) and  $\text{W}(=\text{CHBu}^t)_2(\text{CH}_2\text{Bu}^t)(\text{SiPh}_2\text{Bu}^t)$  (**52**), thereby permitting

the study of direct  $\alpha$ -H exchange between alkylidene and alkylidyne species (equation 18).<sup>90</sup>

Spontaneous loss of  $H_2$  from the  $W^{IV}$  methyl complex,  $[N_3N]WMe$  affords  $[N_3N]W\equiv CH$  (**53**, Scheme 2),<sup>91</sup> and higher alkyl complexes  $[N_3N]WR$  ( $R = Et, Bu$ ) undergo a similar  $\alpha, \alpha$ -dehydrogenation to afford  $[N_3N]W\equiv CR$  and  $H_2$ . The related hydride complex  $[N_3N]WH$  reacts with ethene or propene to yield  $[N_3N]W\equiv CR$  ( $R = Me, Et$ ),<sup>92</sup> or with alkynes  $RC\equiv CPh$  ( $R = H, Ph$ ) to afford diamagnetic 1-tungstenacyclopentene complexes  $[N_3N]W(\eta^2-PhCCHR)$  (**54**, Scheme 2) in which the phenyl ring resides on the alkylidene carbon atom.<sup>92</sup> Among cycloalkyl derivatives,  $[N_3N]W(cyclopropyl)$  evolves ethene to give  $[N_3N]W\equiv CH$ , and  $[N_3N]W(cyclobutyl)$  is converted to  $[N_3N]W\equiv CPr^i$  via an intermediate 1-tungstenacyclopentene complex,  $[N_3N]W(CH=CH_2CH_2CH_2)$ . In contrast, the cyclopentyl complex  $[N_3N]W(C_5H_9)$  is more stable, and in solution it

exists in equilibrium with its cyclopentylidene hydride isomer,  $[N_3N]W(=C_5H_8)(H)$ .<sup>93</sup>

Monomeric alkylidyne complexes,  $(Bu^tO)_3W\equiv CR$  (**56**), have been prepared from  $W_2(OBu^t)_6$  (**55**) and  $RC\equiv CR$  ( $R = Me, Et, Pr^i$ ) via the metathesis reaction shown in equation (19), and a related reductive cleavage of acetonitrile provides the alkylidyne complex (**56**) and a terminal nitrido complex,  $(Bu^tO)_3W\equiv N$ .<sup>94</sup> Generation of  $W_2(OR)_4$  ( $R = SiBu^t_3$ ) in the presence of ethene at low temperature results in cleavage of the ethene  $C=C$  bond to give the bridging alkylidyne complex,  $W_2(OR)_4(\mu-CH)(\mu-CH_2)(\mu-H)$ , which upon warming converts to  $W_2(OR)_4(\mu-CH)_2$  and  $H_2$ .<sup>95</sup> The specific alkylidyne complex,  $(Bu^tO)_3W\equiv CBu^t$ , is an important catalyst for the ring-closing metathesis of alkynes.<sup>96</sup> The structure of  $W_2(\mu-C_2)(OBu^t)_6$  exhibits diyne-like connectivity (i.e.  $W\equiv C-C\equiv W$ ) with a short internal  $C-C$  bond length (see *Bond Length*) of 1.38(2) Å.<sup>97</sup> Interestingly,  $WX_2(PMe_3)_4$  ( $X = Cl, Br$ ) compounds react with vinylsilanes,  $H_2C=CHSiR_3$  ( $R = Me_3, OMe$ ), to yield  $R_3SiX$  and  $W(\equiv CMe)(X)(PMe_3)_4$ ,<sup>98</sup> and these alkylidyne complexes react further with alkynes to form  $W(\equiv CMe)(X)(PMe_3)_2(\eta^2-alkyne)$  derivatives.<sup>99</sup> The unusual silyl complex,  $W(CH_2Bu^t)_2(\equiv CBu^t)[Si(SiMe_3)_3]$ , is synthesized by the reaction of  $W(CH_2Bu^t)_2(\equiv CBu^t)Cl$  with  $LiSi(SiMe_3)_3(THF)_3$ .<sup>100</sup>

Scheme 2

Treatment of  $[Tp^*W(CO)_2(\equiv CPh_3)]^+$  with  $Na[HBET_3]$  in THF affords the amphoteric methylidyne complex,  $Tp^*W(CO)_2(\equiv CH)$ , via the intermediate formyl and carbene complexes,  $Tp^*W(CO)(C(O)H)(\equiv CPh_3)$  and  $Tp^*W(CO)_2(=CH(PPh_3))$ , respectively. Protonation of  $Tp^*W(CO)_2(\equiv CH)$  yields the cationic  $\alpha$ -agostic (see *Agostic Bonding*) methylidyne complex  $[Tp^*W(CO)_2(\equiv CH_2)]^+$ , while deprotonation with alkyl-lithium reagents provides the terminal carbido complex,  $Tp^*W(CO)_2(\equiv CLi)$ , which reacts with electrophiles to generate  $Tp^*W(CO)_2(\equiv CR)$  derivatives ( $R = Me, SiMe_3, I, C(OH)Ph_2, CH(OH)Ph$ , and  $C(O)Ph$ ).<sup>101</sup> Deprotonation of  $Tp^*W(CO)_2(\equiv CMe)$  forms the nucleophilic vinylidene anion,  $[Tp^*W(CO)_2(=C=CH_2)]^-$ , that reacts with  $MeI$  or  $PhC(O)R$  ( $R = H, Me$ ) to afford  $Tp^*W(CO)_2(\equiv CCH_2Me)$

or  $\text{Tp}^*\text{W}(\text{CO})_2(\equiv\text{CCH}_2\text{CR}(\text{OH})\text{Ph})$ , respectively,<sup>102</sup> and protonation of  $\text{CpW}(\text{CO})_2(\equiv\text{CC}\equiv\text{CR})$  with HI produces the alkylidene complexes,  $\text{CpW}(\text{CO})_2(=\text{CHC}\equiv\text{CR})(\text{I})$  ( $\text{R} = \text{Bu}^t, p\text{-Tol}$ ).<sup>103</sup> Similarly, protonation of the  $[\{p\text{-Bu}^t\text{-calix}[4]\text{-(O)}_4\}\text{W}(\equiv\text{CR})]^-$  anion ( $\text{R} = \text{Ph}, \text{Pr}^i, \text{SiMe}_3$ ) leads to the corresponding neutral alkylidene complexes,  $\{p\text{-Bu}^t\text{-calix}[4]\text{-(O)}_4\}\text{W}(=\text{CHR})$ , which may be reversibly deprotonated back to the starting alkylidyne anions by using  $\text{BuLi}$ .<sup>77</sup> Zwitterionic (see *Zwitterion*) alkylidene complexes,  $\text{Tp}^*\text{W}(\text{CO})_2(=\text{C}(\text{CH}_2\text{R})(\text{PPhMe}_2))$  ( $\text{R} = \text{Ph}, \text{CH}=\text{CH}_2$ ), readily lose  $\text{PPhMe}_2$  to form neutral  $\text{Tp}^*\text{W}(\text{CO})_2(\equiv\text{CCH}_2\text{R})$ , and deprotonation of these complexes with a strong base occurs at  $\text{C}_\beta$  to form the reactive vinylidene anions,  $[\text{Tp}^*\text{W}(\text{CO})_2(=\text{C}=\text{CHR})]^-$ .<sup>104</sup>

The photooxidation of tungsten-alkylidyne complexes results in the formation of organic products derived from the carbyne substituent (e.g. equation 20). These reactions involve a 1e oxidation of the alkylidyne reactant to form a 17e radical cation species, followed by H atom abstraction from the solvent, to yield a cationic alkylidene complex that may undergo a [1,2]-H shift to afford an  $\eta^2$ -alkene compound. Photooxidation of the cyclohexenyl alkylidyne complex,  $\text{CpW}(\text{CO})(\text{PR}_3)(\equiv\text{CC}_6\text{H}_{10})$  ( $\text{R} = \text{OMe}$ ) (**57**), in  $\text{CHCl}_3$  affords the stable  $\eta^3$ -vinylcarbene complex,  $\text{CpWCl}(\text{PR}_3)(=\text{CHC}_6\text{H}_{10})$  (**58**) (equation 21), thereby providing the first direct evidence for alkylidene intermediates in the single-electron oxidation reactions of alkylidyne complexes.<sup>105,106</sup>

### 3.2 $\eta^2$ -Hydrocarbon Complexes

#### 3.2.1 Alkene Complexes

Tungsten-alkene bonding is best described by the Dewar–Chatt–Duncanson model (see *Dewar–Chatt–Duncanson Bonding Model*) in which  $\sigma$ -type electron donation from the alkene  $\pi$  orbital occurs along with  $\pi$ -backbonding (see *Back Bonding*) from a metal  $d\pi$  orbital into the empty  $\pi^*$  orbital of the alkene. According to this synergistic bonding model,  $\eta^2$ -coordination results in a decrease in the alkene C–C bond order (see *Bond Order*). For this reason, complexes

containing  $\eta^2$ -alkene ligands may be viewed in the limit as either planar alkene adducts (**E**) or metallacyclopropane (**F**) complexes.

Tungsten-alkene complexes (see *Alkene Complexes*) are typically prepared by ligand-substitution reactions under thermal or photolytic conditions. For example, photolysis of  $\text{W}(\text{CO})_6$  in the presence of an alkene provides simple  $\text{W}(\text{CO})_{6-n}(\eta^2\text{-alkene})_n$  ( $n = 1, 2$ ) complexes, and irradiation of these species gives rise to two competitive primary photoprocesses, that is, alkene and CO dissociation.<sup>107</sup> The labile (see *Labile*) ethene complexes,  $\text{W}(\text{CO})_5(\eta^2\text{-C}_2\text{H}_4)$  and *cis*- $\text{W}(\text{CO})_4(\eta^2\text{-C}_2\text{H}_4)_2$ , have been characterized only at low temperatures in ethene-saturated hydrocarbon solutions. However, *trans*- $\text{W}(\text{CO})_4(\eta^2\text{-C}_2\text{H}_4)_2$  (**59**,  $\text{L} = \text{CO}$ ) is thermally stable and possesses  $D_{2d}$  symmetry, with the ethene ligands in a *trans*, orthogonal conformation that maximizes the efficiency of tungsten to alkene ( $\pi^*$ ) back donation.<sup>108</sup> Photolysis of (**59**) ( $\text{L} = \text{CO}$ ) in the presence of  $\text{H}_2$  at  $-90^\circ\text{C}$  results in the formation of the dihydrogen complexes, *mer*- $\text{W}(\text{CO})_3(\eta^2\text{-H}_2)(\eta^2\text{-C}_2\text{H}_4)_2$  and *cis*- $\text{W}(\text{CO})_4(\eta^2\text{-H}_2)(\eta^2\text{-C}_2\text{H}_4)$ .<sup>109</sup>

The alkene derivatives, *cis*- $\text{W}(\text{CO})_4(\text{PR}_3)(\eta^2\text{-alkene})$  ( $\text{R} = \text{alkyl or aryl}$ ), are typically prepared by ligand substitution (see *Ligand Substitution*) from  $\text{W}(\text{CO})_4(\text{L})(\text{PR}_3)$  ( $\text{L} = \text{Lewis base}$ ), whereas the related compounds,  $\text{W}(\text{CO})_3(\text{PR}_3)_2(\eta^2\text{-alkene})$ , are readily accessed via photolysis of  $\text{W}(\text{CO})_4(\text{PR}_3)_2$  in the presence of an alkene. The bis(ethene) complex, *trans*- $\text{W}(\text{PMe}_3)_4(\eta^2\text{-C}_2\text{H}_4)_2$  (**59**,  $\text{L} = \text{PMe}_3$ ), reversibly eliminates  $\text{PMe}_3$  in solution,<sup>110</sup> and the coordinatively unsaturated  $\text{W}(\text{PMe}_3)_3(\eta^2\text{-C}_2\text{H}_4)_2$  fragment reacts with Lewis bases,  $\text{L}$ , to yield complexes of the type *mer,trans*- $\text{W}(\text{L})(\text{PMe}_3)_3(\eta^2\text{-C}_2\text{H}_4)_2$  or *trans*- $\text{W}(\text{L})_2(\text{PMe}_3)_2(\eta^2\text{-C}_2\text{H}_4)_2$  ( $\text{L} = \text{CNR}, \text{CO}$ ). More interesting are the reactions of (**59**) ( $\text{L} = \text{PMe}_3$ ) and related complexes containing bidentate (see *Bidentate*

*Ligand*) phosphine ligands with CS<sub>2</sub> or CO<sub>2</sub>, which lead to coupled products containing  $\eta^3$ -C<sub>2</sub>S<sub>4</sub> or acrylate ligands, respectively.<sup>111,112</sup> The reactions of WCl<sub>2</sub>(PR<sub>3</sub>)<sub>4</sub> with alkenes provide the bis(alkene) complexes, *cis,trans*-WCl<sub>2</sub>(PR<sub>3</sub>)<sub>2</sub>( $\eta^2$ -alkene)<sub>2</sub>, in which the *cis*-alkene ligands are oriented parallel to one another. The oxo, sulfido, and imido complexes, WCl<sub>2</sub>(E)(PR<sub>3</sub>)<sub>2</sub>( $\eta^2$ -alkene) (E = O, S, NPh) possess alkene ligands that are *cis* to the  $\pi$ -ligand E and are oriented perpendicular to the W=E linkage.

Alkene complexes (*see Alkene Complexes*) can also be formed from tungsten-alkyl complexes via  $\beta$ -H migration. Thus, photolysis of CpW(CO)<sub>3</sub>(Et) results in the elimination of CO and the transient formation of CpW(CO)<sub>2</sub>(H)( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>), and time-resolved infrared spectroscopic (*see Infrared Reflection Adsorption Spectroscopy*) studies indicate that this species undergoes *cis* to *trans* isomerization prior to the elimination of ethene and uptake of CO to yield CpW(CO)<sub>3</sub>(H).<sup>113</sup> Although a vacant coordination site is usually required for such transformations to occur, examples of ligand-induced  $\beta$ -H transfer have been reported for a series of W<sup>VI</sup> dialkyl complexes.<sup>114</sup> Finally, the reaction of W(OMe)<sub>3</sub>Cl<sub>3</sub> with excess EtLi followed by the addition of tmeda yields [Li(tmeda)]<sub>3</sub>[WH( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>)<sub>4</sub>] (i.e. [Li(tmeda)]<sub>3</sub>[(**60**)], presumably via thermal decomposition of an undetected ethyl complex. The anion [(**60**)]<sup>3-</sup> is trigonal-bipyramidal in the solid state, with two mutually perpendicular ethene ligands in the axial sites and two coplanar ethene ligands and a hydride ligand constituting the equatorial plane.<sup>115</sup>

Protonation of *trans*-W(dppe)<sub>2</sub>( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>)<sub>2</sub> with HX (X = Cl, Br) results in the formation of the cationic hydrido complexes, [*trans*-WH(dppe)<sub>2</sub>( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>)<sub>2</sub>]<sup>+</sup>X<sup>-</sup>, and stopped-flow kinetic studies have shown that these reactions proceed via two parallel pathways involving either slow protonation at tungsten or rapid protonation of the ethene ligand followed by slow  $\beta$ -H elimination (*see  $\beta$ -Elimination*) from an intermediate ethyl complex.<sup>116</sup> The interesting reaction of Cp<sub>2</sub>W( $\eta^2$ -C<sub>2</sub>H<sub>4</sub>) with perfluoro-*tert*-butyl iodide results in fluoroalkylation of the ethene ligand and formation of Cp<sub>2</sub>W[CH<sub>2</sub>CH<sub>2</sub>C(CF<sub>3</sub>)<sub>3</sub>]<sup>+</sup>I<sup>-</sup>.<sup>117</sup>

Metallacyclopentane complexes are obtained similarly by reductive coupling (*see Reductive Coupling*) of alkene ligands,<sup>77,79</sup> by reduction of the ester functionalities in CpW( $\eta^2$ -C<sub>2</sub>H<sub>2</sub>R<sub>2</sub>) (R = CO<sub>2</sub>Me),<sup>118</sup> or via intramolecular (*see Intramolecular*) hydrogen transfer in an alkyl-vinyl complex.<sup>119</sup> Formal addition of an alkene across a W=C bond gives rise to metallacyclobutane complexes that are intermediates in catalytic alkene metathesis (*see Alkene Metathesis*) reactions.<sup>85,120,121</sup> Cycloalkene adducts are believed to be intermediates in ROMP reactions (*see Ring Opening Metathesis Polymerization Reactions*), and the solid-state molecular structure of the cycloheptene adduct (**61**) (X = GaBr<sub>4</sub>) provides convincing evidence for the existence of intermediate alkene complexes in ROMP

catalysis (equation 22).<sup>122</sup>

The ditungsten-hexakis(alkoxide) complexes, W<sub>2</sub>(OR)<sub>6</sub>, react with ethene to give initially the bis(ethene) adduct (**62**) when R = CH<sub>2</sub>Bu<sup>t</sup> or the metallacyclopentane complex (**63**) when R = Pr<sup>t</sup>. These isolable intermediates are eventually converted to the 1-metallacyclopentene complex (**64**), which is formed by  $\alpha$ -H transfer from the metallacyclopentane ring of (**63**) to the coordinated ethene ligand.<sup>94</sup> A variety of alkene rearrangements also occur in tungsten complexes containing calixarene (*see Calixarenes*) ligands, including deprotonation of an  $\eta^2$ -alkene ligand to give 1-metallacyclopentene or alkylidyne derivatives, and reductive coupling (*see Reductive Coupling*) to form metallacyclopentanes.<sup>77</sup>

Other types of tungsten-alkene complexes that merit mention include the first group six  $\eta^2$ -benzene complex, TpW(NO)(PMe<sub>3</sub>)( $\eta^2$ -C<sub>6</sub>H<sub>6</sub>), that contains a  $\pi$ -bound benzene ligand activated toward Diels-Alder cycloaddition.<sup>123</sup> Also, the  $\eta^2$ -fullerene complexes, *mer*-W(CO)<sub>3</sub>(L-L)( $\eta^2$ -C<sub>60</sub>) (**65**), have been prepared from W(CO)<sub>4</sub>(L-L) (L-L = a bidentate N- or P-donor ligand) in the presence of C<sub>60</sub>.<sup>124,125</sup> In some cases, a bimetallic complex in which two metal centers are attached to a single fullerene (*see Buckminsterfullerene*) moiety, that is, [*mer*-W(CO)<sub>3</sub>(L-L)]<sub>2</sub>( $\eta^2$ ,  $\eta^2$ -C<sub>60</sub>), (**66**) is also formed, and analogous complexes containing C<sub>70</sub> have also been prepared.<sup>125</sup> The dumbbell-shaped complex, W( $\eta^2$ -C<sub>60</sub>)<sub>2</sub>(CO)<sub>2</sub>(L-L) (**67**, L-L = 4,4'-di(butylcarboxyl)-2,2'-bipyridine), contains two C<sub>60</sub> ligands, each of which is coordinated to the metal center in an  $\eta^2$ -fashion.<sup>126</sup>

### 3.2.2 Alkyne Complexes

Alkynes may function as 2e alkene analogues or as formal 4e donor ligands. This situation arises because an alkyne can engage a metal center using not only the  $\pi$  and  $\pi^*$  orbitals involved in  $\sigma$ -donor and  $\pi$ -acceptor bonding, but also by employing a second  $\pi$  orbital oriented perpendicular to the tungsten-alkyne bond axis; these are known as  $\pi_{\parallel}$  and  $\pi_{\perp}$  interactions, respectively. In low-valent,  $d^6$  (see *d<sup>n</sup> Configuration*) tungsten complexes, alkyne ligands generally act as 2e donors since repulsive interactions between the alkyne  $\pi_{\perp}$  orbital and filled metal  $d\pi$  orbitals dictate the geometry and reactivity of the complexes. In  $d^4$  and  $d^2$  tungsten complexes, the  $\pi_{\perp}$  orbital may interact with an empty metal  $d$  orbital to form an additional  $\pi$ -donor bond, and the alkyne then acts as a formal 4e donor ligand.<sup>127</sup> In complexes containing more than one alkyne ligand, the  $\pi_{\perp}$  orbitals may donate electron density into the same metal  $d\pi$  orbital, thus giving rise to formal electron donor counts between two and four. The unique ability of an ancillary alkyne ligand to

function as a variable (i.e. three or four) electron donor in the presence of competing  $\pi$ -ligands can lead to very interesting reaction chemistry, for example, in the stepwise oxidation of a benzylamine ligand to a benzonitrile ligand via isolable amido, imine, and azavinylidene intermediate complexes on the  $[\text{Tp}^*\text{W}(\text{CO})(\eta^2\text{-HC}\equiv\text{CPh})]^+$  fragment (Scheme 3).<sup>128</sup> Regio- and stereoselective reactions of  $\eta^2$ -alkyne ligands, followed by their removal from the metal fragment, have provided synthetic routes to chiral alkynes that are difficult to prepare by conventional means.<sup>129</sup> The subsequent material in this section is divided into  $\text{W}^0$ ,  $\text{W}^{\text{II}}$ , and  $\text{W}^{\text{IV/VI}}$  subsections.

Zero-valent tungsten complexes containing one, two, or three alkyne ligands are known. Photochemical and thermal reactions of  $\text{W}(\text{CO})_6$  with alkynes lead to thermally unstable  $\text{W}(\text{CO})_{6-n}(\eta^2\text{-alkyne})_n$  ( $n = 1, 2$ ) species, and those containing terminal alkyne ligands (**G**) often undergo a formal [1,2]-*H* shift to afford vinylidene complexes  $\text{W}(\text{CO})_5(=\text{C}=\text{CHR})$  (**H**).<sup>130</sup> This mode of reactivity also occurs during the isomerization of *fac*- $[\text{W}(\text{CO})_3(\text{dppe})(\eta^2\text{-HC}\equiv\text{CR})]$  ( $\text{R} = \text{H}, \text{Ph}, n\text{-Bu}$ ) to *mer*- $[\text{W}(=\text{C}=\text{CHR})(\text{CO})_3(\text{dppe})]$ , and it is attributed to unfavorable repulsion between the alkyne  $\pi_{\perp}$  orbital and a filled metal  $d\pi$  orbital.<sup>131</sup> Theoretical studies of the mechanism of acetylene–vinylidene rearrangement have shown that model tungsten complexes containing these ligands are best formulated as metallacyclopentene (**I**) and metallaallene species, respectively,<sup>132</sup> and it should be noted that vinylidene complexes may also be prepared by the addition of electrophiles to tungsten–alkynyl complexes or by deprotonation of alkylidyne complexes.<sup>133</sup> Vinylidene ligands are among the

Scheme 3

strongest  $\pi$ -acceptor ligands known, and they have found use as catalysts in [2 + 2] cycloaddition and alkyne dimerization reactions.<sup>134</sup>

Bis(alkyne) complexes of  $W^0$  generally have the compositions  $W(CO)_2(L-L)(\eta^2-RC\equiv CR)_2$  ( $L-L$  = a bidentate N- or P-donor ligand) and invariably contain *cis* CO ligands and mutually *trans*, orthogonal alkyne ligands.<sup>135</sup> The crucial presence of electron-withdrawing alkyne substituents (i.e.  $R = CO_2Me, CO_2Et$ ) is thought to enhance tungsten  $d\pi$  to alkyne  $\pi_{||}^*$  backbonding (see *Back Bonding*) and delocalize alkyne  $\pi_{\perp}$  electron density. Consequently, the alkyne ligands in these complexes function as formal 2e donors.

Thermally stable  $W(CO)(\eta^2-alkyne)_3$  complexes, in which the three alkyne ligands contribute a total of 10 electrons to the metal center, may be prepared from suitable tricarbonyl precursors,<sup>136</sup> and the apical CO ligand can be replaced with other neutral Lewis bases (see *Lewis Acids & Bases*).<sup>137</sup>  $W(PMe_3)(\eta^2-HC\equiv CPh)_3$  may be prepared via this method or by the reduction of  $WCl_4(PMe_3)_2$  in the presence of  $HC\equiv CPh$ .<sup>138</sup> Alkyne-alkyne coupling occurs when  $W(L)(\eta^2-PhC\equiv CPh)_3$  ( $L = CO, MeCN$ ) is treated with excess  $PhC\equiv CPh$ , resulting in the formation of  $(\eta^4-C_4Ph_4)W(L)(\eta^2-PhC\equiv CPh)_2$  and related carbocyclic derivatives.<sup>137</sup> The labile (see *Labile*) acetonitrile complex,  $W(MeCN)(\eta^2-PhC\equiv CPh)_3$  (**68**), undergoes rearrangement upon reaction with *o*- $Ph_2PC_6H_4CH=CH_2$  via cleavage of both  $C=C$  and  $C\equiv C$  bonds to yield  $(\eta^5-C_5Ph_4H)W(\equiv CPh)(Ph_2PC_6H_4CH=CHPh)$  (**69**) (equation 23).<sup>139</sup>

Numerous  $W^{II}$  complexes of the type  $W(CO)_{3-n}(L)_n(X)_2$  ( $\eta^2-alkyne$ ) ( $n = 1, 2$ ) are known, most of which have been prepared from reactions of appropriate  $W^{II}$  or  $W^{III}$  precursors with an alkyne.<sup>127</sup> Thus, reduction of  $WCl_3(PMe_3)_2(\eta^2-alkyne)$  in the presence of a Lewis base (see *Lewis Acids & Bases*) generates  $WCl_2(PMe_3)_2(L)(\eta^2-alkyne)$ . Alkyne ligands may also be prepared via intramolecular (see *Intramolecular*) coupling of alkylidyne, isocyanide, and carbonyl ligands, or by treating the alkynyl anions,  $[CpW(NO)(CO)(C\equiv CR)]^-$ , with an electrophile (see *Electrophile*).<sup>140</sup> Simple alkyne complexes

such as  $CpW(CO)(X)(\eta^2-alkyne)$  or  $W(S_2CNR_2)_2(L)(\eta^2-alkyne)$  react with excess alkyne under forcing conditions to yield bis(alkyne) derivatives,  $CpW(X)(\eta^2-alkyne)_2$  and  $W(S_2CNR_2)_2(\eta^2-alkyne)_2$ , in which the alkyne ligands are oriented parallel to one another in order to facilitate  $\pi$  donation from both alkynes into the same  $d\pi$  orbital (i.e. each alkyne ligand acts as a formal 3e donor). Related  $W^{II}$  bis(alkyne) complexes,  $W(CO)(X)_2(L)(\eta^2-RC\equiv CR)_2$ , are prepared by the reactions of  $W(CO)_3(X)_2(L)_2$  with alkynes, and ligand substitution generates cationic  $[W(CO)(X)(L-L)(\eta^2-RC\equiv CR)_2]^+$  derivatives. Alternatively, reduction of  $Cp^*WX_4$  in the presence of two equivalents of an alkyne affords  $Cp^*WX(\eta^2-alkyne)_2$ .<sup>141</sup>

Alkyne ligands are susceptible to attack by nucleophiles, which typically leads to the formation of  $\eta^2$ -vinyl complexes;<sup>47</sup> this is particularly true in the case of electron-deficient alkynes. Noteworthy in this regard are the reactions of  $[Tp^*W(CO)_2(\eta^2-RC\equiv CR')]^+$  cations with hydride reagents that yield  $\eta^2$ -vinyl,  $\eta^2$ -allene, or  $\eta^3$ -allyl complexes depending upon the nature of the alkyne substituents.<sup>49</sup>

Interestingly, the properties of some high oxidation state tungsten-alkyne complexes indicate that there has been considerable transfer of electron density to the alkyne ligands. For instance, the  $W(4f_{7/2})$  binding energy (determined by X-ray photoelectron spectroscopy) of  $[WCl_4(\eta^2-PhC\equiv CPh)]_2$  is similar to that measured for the  $d^0$  (see *d<sup>n</sup> Configuration*) imido complex,  $[WCl_4(NPh)]_2$ , and is in agreement with a  $W^{VI}$  oxidation state.<sup>142</sup> Similarly, computational investigations support the experimental evidence that  $WCl_3(\eta^2-PhC\equiv CPh)(PMe_3)_2$  and  $WCl_2(\eta^2-PhC\equiv CPh)(PMe_3)_3$  are appropriately formulated as complexes of  $W^V$  and  $W^{IV}$ , respectively. Given these observations, the description of the related  $[WCl_2(\eta^2-HC\equiv CH)(MeCN)_3]^+$  as a monomeric  $W^{III}$  complex is by no means certain.<sup>143</sup> Consistent with their anionic character, the alkyne ligands in  $[WCl_4(\eta^2-PhC\equiv CPh)]_2$  undergo ready hydrolysis to form free *cis*-stilbene. A great many  $W^{IV}$  alkyne complexes containing alkylidene, imido, oxo, and sulfido ligands are also known, and the alkyne ligands in these complexes, like the alkene ligands in related complexes described in a previous section (vide supra), are generally coordinated *cis* to the  $\pi$ -donor ligand and perpendicular to its multiple bond with tungsten.

The ditungsten-hexakis(alkoxide) complexes,  $W_2(OR)_6$ , exhibit a wide range of reactivity toward alkynes. Thus, when  $R = Bu^t$ , reaction with  $PhC\equiv CPh$  yields a mixture of  $W_2(OR)_4(\mu-PhC\equiv CPh)_2$  and  $W_2(OR)_4(\mu-CPh)_2$ , but the analogous reaction with ethyne produces  $W_2(OR)_6(\mu-HC\equiv CH)(L)$  (**70**) in the presence of  $L =$  pyridine. When  $R = OSiMe_2Bu^t$ , the elimination of  $ROH$  from complex (**70**) affords the  $\mu$ - $\eta^2$ -ethynyl complex,  $W_2(OR)_5(\mu-C_2H)$  (**71**), and the liberated alcohol converts any remaining (**70**) to a mixture of the vinyl and ethylidyne isomers,  $W_2(OR)_7(\mu-CHCH_2)$  (**72**) and  $W_2(OR)_7(\mu-CMe)$  (**73**), which are related by a [1,2]-*H* shift but do not interconvert in solution

Scheme 4

(Scheme 4).<sup>94</sup> In contrast, the addition of ethyne to  $W_2(OR)_8$  ( $R = CH_2Bu^t$ ) yields an unusual 1:1 adduct in which the bridging  $\mu, \eta^2-HC\equiv CH$  ligand is neither parallel nor perpendicular to the W–W bond.<sup>144</sup>

### 3.3 $\eta^3$ -Hydrocarbon Complexes

Tungsten–allyl complexes may be prepared by metathesis from suitable halide precursors using allyl Grignard reagents (see *Grignard Reagents*) or from the reactions of  $[CpW(NO)(CO)(C\equiv CR)]^-$  ( $R = Ph, Bu^t, SiMe_3$ ) with allylic halides.<sup>56</sup> The homoleptic (see *Homoleptic Compound*) allyl complex,  $W(\eta^3-C_3H_5)_4$ , has been known for many years, but questions as to its exact structure have remained unanswered until recently. A thorough analysis by Casey and coworkers has shown that the molecular structure that best agrees with the NMR spectroscopic data is one in which the complex has  $S_4$  symmetry (74).<sup>145</sup> The tris(allyl) dimer,  $[(\eta^3-C_3H_5)_3WCl]_2$ , reacts with methyl-substituted allylmagnesium halides to form  $(\eta^3-C_3H_5)_3W(\eta^3-MeC_3H_4)$  and  $(\eta^3-C_3H_5)_3W(\eta^3-1,3-Me_2C_3H_3)$  as a mixture of isomers and with alkylmagnesium halides to give  $\beta$ -agostic (see *Agostic Bonding*) alkyl complexes,  $(\eta^3-C_3H_5)_3W(R)$ . The reaction of  $(\eta^3-C_3H_5)_3W(Et)$  with  $PMe_3$  initiates an intramolecular (see *Intramolecular*) protonation of an allyl group to give  $(\eta^3-C_3H_5)_2W(\eta^2-CH_2=CH_2)(PMe_3)_2$  and propene, and the ethyl complex also readily inserts  $CNBU^t$  into its W–C link to form  $(\eta^3-C_3H_5)_3W(\eta^2-EtC=NBu^t)$ .<sup>146</sup> Finally, the reaction of  $WCl_2(PMe_3)_4$  with  $Me_3SiOCH_2CH=CH_2$  affords  $Me_3SiCl$  and the oxo allyl complex,  $WCl(O)(\eta^3-C_3H_5)(PMe_3)_2$ .<sup>147</sup>

Thermal  $\alpha$ -elimination (see  *$\alpha$ -Elimination*) of neopentane from the dimethylallyl complex,  $Cp^*W(NO)(CH_2Bu^t)(\eta^3-Me_2C_3H_3)$ , generates a reactive 16e  $\eta^2$ -allene intermediate that activates hydrocarbon solvent C–H bonds to

yield  $Cp^*W(NO)(R)(\eta^3-Me_2C_3H_3)$  ( $R = Ph, CH_2SiMe_3$ ).<sup>75</sup> In cyclohexane, three C–H bonds of the solvent are activated to give the  $\eta^3$ -cyclohexenyl complex,  $Cp^*W(NO)(\eta^3-C_6H_9)(H)$  (75),<sup>148</sup> and related  $\eta^3$ -allyl hydrido complexes,  $Cp^*W(NO)(\eta^3-C_7H_{11})(H)$  (76) and  $Cp^*W(NO)(\eta^3-C_8H_{13})(H)$  (77), are formed from  $Cp^*W(NO)(CH_2Bu^t)_2$  upon thermolysis in methylcyclohexane or ethylcyclohexane, respectively.<sup>75</sup> Irradiation of  $Tp^*W(CO)_3(H)$  in the presence of unconjugated dienes or alkynes generates  $\eta^3$ -allyl complexes, that is,  $Tp^*W(CO)_2(\eta^3-CH_2RCHCH_2R')$ , via insertion into the W–H bond.<sup>149</sup> The reactions of *cis*- $Cp^*W(CO)_2(Me)(MeCN)$  with  $HSiMe_2(CH=CR_2)$  ( $R = H, Me$ ) afford novel  $\eta^3$ -1-silaallyl complexes,  $Cp^*W(CO)_2(\eta^3-Me_2SiCHCR_2)$ , via thermal Si–H bond activation.<sup>150</sup> Reaction of  $[Tp^*W(=CH_2)(CO)(L)]^+$  with excess base yields the unusual allyl-bridged dimer,  $[Tp^*W(CO)(L)]_2(\mu-C_3H_5)^+$  (78,  $L = \eta^2-PhC\equiv CMe$ ), which is inert toward a variety of nucleophiles.<sup>151</sup>

(78)

The ditungsten complex,  $W_2(C_3H_5)_2(NMe_2)_4$  (**79**), has  $C_2$  symmetry in the solid state with bridging allyl ligands that exhibit an unusual  $\mu-\eta^1:\eta^2$ -2-propenyl coordination mode,<sup>152</sup> and the reaction of  $W_2(OR)_8$  with allene generates the  $W_2(OR)_8(\mu-\eta^1,\eta^3-C_3H_4)$  adduct (**80**,  $R = CH_2Bu^t$ ).<sup>153</sup>

(79)

(80)

Substituted allyl complexes of the type  $Cp^*W(CO)_2(\eta^3\text{-allyl})$  are useful synthetic reagents, and their organic chemistry has been reviewed.<sup>62</sup> The reaction of  $Cp^*W(CO)_3(\eta^1\text{-trans-CH}_2\text{CH=CHC}\equiv\text{CMe})$  (**81**) with ROH ( $R = H, Me$ ) over  $SiO_2$  affords  $Cp^*W(CO)_2(\eta^3\text{-3-syn-CO}_2R\text{-3-anti-Me-1-vinylallyl})$  compounds (**82**), thereby providing the only direct evidence available for tandem 1,3-metal shifts across conjugated allyl and alkyne bonds (equation 24).<sup>154</sup>

(24)

### 3.4 $\eta^4$ -Hydrocarbon Complexes

The complexes  $W(\eta^4\text{-diene})_n(CO)_{6-2n}$  ( $n = 2$ , diene = 1,3-butadiene, (**83**);  $n = 3$ , diene = 2,3-dimethylbutadiene, **84**) have been prepared, and their solid-state molecular structures have been determined. Interestingly, the two diene ligands in (**83**) are twisted relative to one another, imparting  $C_2$  symmetry to the complex.<sup>155</sup> Homoleptic (**84**) has been the subject of a detailed theoretical investigation<sup>156</sup> in an attempt to explain its rare trigonal–prismatic coordination

geometry.<sup>157</sup> The related carbonyl species,  $W(CO)_4(\eta^4\text{-1,3-butadiene})$ , can be generated transiently in solution, but it has not yet been isolated.<sup>158</sup>

(83)

(84)

Many diene complexes (*see Diene Complexes*) having the general composition  $W(\eta^4\text{-diene})(CO)_{4-n}(L)_n$  (e.g.  $n = 2$ , **85**) are known, as are  $Cp^*W(\eta^4\text{-diene})(CO)(R)$  species (**86**,  $L = \text{Lewis base}$ ,  $R = \text{alkyl, acyl}$ ). Hydrogenation of  $Cp^*W(NO)(CH_2SiMe_3)_2$  in the presence of acyclic, conjugated dienes leads to the formation of a variety of  $Cp^*W(NO)(\eta^4\text{-trans-diene})$  complexes, and when 1,3-cyclooctadiene is employed as the diene substrate, it undergoes an unprecedented coupling to afford the triene complex (**87**).

(85)

(86)

(87)

Several  $\eta^4$ -norbornadiene (nbd) complexes containing the  $W(CO)_x$  fragment are also known, among them  $W(CO)_4(\eta^4\text{-nbd})$  and complexes of the type  $W(CO)_2(X)_2(\eta^4\text{-nbd})$ .<sup>159</sup> Finally, several tungsten–cyclobutadiene complexes have been described, and they are generally formed by the coupling of two alkyne ligands, as in the case of  $(\eta^4\text{-C}_4\text{Ph}_4)W(\eta^2\text{-PhC}\equiv\text{CPh})_2(CO)$  (**88**).<sup>160</sup>

(88)

### 3.5 $\eta^5$ -Hydrocarbon Complexes

#### 3.5.1 Tungstenocene-derived Complexes

Tungstenocene ( $\text{Cp}_2\text{W}$ ) is very reactive once generated by photolysis of  $\text{Cp}_2\text{WH}_2$  or by thermolysis of  $\text{Cp}_2\text{W}(\text{Me})\text{H}$ ,<sup>161</sup> and it inserts readily into C–H, O–H or B–B<sup>162</sup> bonds. The dihydride,  $\text{Cp}_2\text{WH}_2$ , is a strong Lewis base (see *Lewis Acids & Bases*), and it reacts with Lewis acids including  $\text{AgBF}_4$  to form adducts, for example  $[(\text{Cp}_2\text{WH}_2)_2\text{Ag}]\text{BF}_4$ , bridged by the hydrido ligands.<sup>163</sup> Chlorination of  $\text{Cp}_2\text{WH}_2$  with  $\text{CHCl}_3$  (or the reaction of  $\text{WCl}_4(\text{DME})$  with  $\text{LiCp}$ ) affords  $\text{Cp}_2\text{WCl}_2$ , which can be oxidized to  $[\text{Cp}_2\text{WCl}_2]^{2+}$ .<sup>164</sup> The dichloro complex serves as an excellent entry point into related tungstenocene chemistry;<sup>165</sup> for example, alkyl derivatives are prepared by halide metathesis, and the electronic structures of  $\text{Cp}_2\text{WR}_2$  species have recently been described in detail.<sup>166</sup> The related oxo complex,  $\text{Cp}_2\text{W}(\text{O})$ , has been the subject of a detailed thermochemical and theoretical investigation in order to understand its  $[2 + 2]$  cycloaddition reactions.<sup>167</sup> The intramolecular (see *Intramolecular*) thermal rearrangement of  $\text{W}(\eta^2\text{-PhC}\equiv\text{CPh})(\eta^8\text{-C}_8\text{Ph}_8)$  (**89**) results in the formation of the isolable perphenylated tungstenocene,  $(\eta^5\text{-C}_5\text{Ph}_5)_2\text{W}$  (**90**) (equation 25),<sup>137</sup> and the tungstenocenium cations,  $[(\eta^5\text{-C}_5\text{Ph}_5)_2\text{W}]^+$  and  $[(\eta^5\text{-C}_5\text{Ph}_5)_2\text{W}]^{2+}$ , may be generated by oxidation of the neutral compound.<sup>168</sup>

The *ansa*-tungstenocene complex,  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)_2]\text{W}(\text{Me})\text{H}$ , also eliminates methane upon thermolysis in benzene and forms the phenyl complex  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)_2]\text{W}(\text{Ph})\text{H}$ . Careful experimental work by Parkin and coworkers has established the existence of an inverse equilibrium isotope effect (see *Isotope Effect*) during this reaction.<sup>169</sup> This work follows a related study by Norton and coworkers on  $\text{Cp}_2\text{W}(\text{Me})\text{H}$  that revealed similar results.<sup>170</sup> This C–H activation chemistry has also attracted the interest of theoretical chemists.<sup>166</sup> The intramolecular (see *Intramolecular*) H/D exchange observed in  $[\text{Me}_2\text{C}(\eta^5\text{-C}_5\text{H}_4)_2]\text{W}(\text{R})\text{H}$  complexes containing adjacent alkyl and hydrido ligands has provided compelling evidence for the existence of intermediate  $\sigma$ -alkane complexes of tungsten.<sup>171</sup>

#### 3.5.2 Non-tungstenocene-derived Complexes

As amply illustrated throughout this article, the pentamethylcyclopentadienyl ligand ( $\text{Cp}^*$ ) effectively stabilizes

many types of organometallic complexes of tungsten. However, on occasion, it can undergo intramolecular (see *Intramolecular*) C–H activation to afford so-called ‘tuck-in’ complexes. For instance, upon reaction of  $\text{Cp}^*\text{W}(\text{NR})_2\text{Cl}$  with  $\text{LiNHR}$ , the initially formed amido complex,  $\text{Cp}^*\text{W}(\text{NR})_2(\text{NHR})$  (**91**), eliminates amine to afford the  $\eta^1, \eta^5\text{-CH}_2\text{C}_5\text{Me}_4$  complex (**92**) (equation 26,  $\text{R} = 2,6\text{-Pr}^i_2\text{C}_6\text{H}_3$ ).<sup>172</sup>

The cyclopentadienyl tungsten–chloro complexes,  $[\text{Cp}^*\text{W}]_2(\mu\text{-Cl})_4$  (**93**) and  $\text{Cp}'\text{Cl}_2\text{W}\equiv\text{WCl}_2\text{Cp}'$  (**94**,  $\text{Cp}' = \eta^5\text{-C}_5\text{H}_4\text{R}$ ),<sup>173</sup> are important precursors for the synthesis of other organometallic compounds.<sup>174</sup> High-yield syntheses of  $\text{Cp}'\text{WCl}_4$  and related imido complexes, including  $\text{Cp}'\text{WCl}_3(\text{NBU}^t)$  and  $17e \text{ Cp}'\text{WCl}_2(\text{NBU}^t)$ , have also been reported ( $\text{Cp}' = \text{Cp}, \text{Cp}^*$ ).<sup>161,175</sup> The tetrachloro complex,  $\text{Cp}^*\text{WCl}_4$  (**95**), has been used to prepare the organometallic fluoride complex,  $\text{Cp}^*\text{WF}_5$  (**96**),<sup>176</sup> and the square–pyramidal tetramethyl complex,  $\text{Cp}^*\text{WMe}_4$  (**97**),<sup>177</sup> that rearranges upon oxidation to give the trigonal–bipyramidal cation,  $[\text{Cp}^*\text{WMe}_4]^+$ .<sup>178</sup> Terminal chalcogenide derivatives  $[\text{Cp}^*\text{WE}_3]^-$  ( $\text{E} = \text{O}, \text{S}, \text{Se}$ ) are known, and chiral  $[\text{Cp}^*\text{W}(\text{O})(\text{S})(\text{Se})]^-$  can be prepared by treating  $\text{Cp}^*\text{W}(\text{S})_2\text{Cl}$  sequentially with  $\text{H}_2\text{O}$  and diselenide reagents.<sup>179</sup> Finally, related oxo and sulfido derivatives including  $\text{Cp}^*\text{W}(\text{O})_2\text{Cl}$  and  $[\text{Cp}^*\text{WS}_3]^-$  have been used as reagents for the synthesis of cluster complexes<sup>180–182</sup> (see *Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements*).

Important advances in the field of C–H bond activation have involved the photochemical reactions of boryl complexes such as  $\text{Cp}^*\text{W}(\text{CO})_3(\text{Bcat})$  (**98**, cat = 1,2- $\text{O}_2$ -3,5- $\text{Me}_2\text{C}_6\text{H}_2$ ). Transient species derived from these complexes efficiently activate the C–H bonds of alkanes and arenes (see *Alkane Carbon–Hydrogen Bond Activation*), and they can convert hydrocarbon solvents into alkylboronate esters (equation 27).<sup>183,184</sup> Experimental and theoretical studies have shown that these reactions proceed via a boron-assisted,  $\sigma$ -bond metathesis (see  *$\sigma$ -Bond Metathesis*) pathway involving back donation of electron density from the tungsten atom to a formally unoccupied p orbital centered on the boryl ligand.<sup>185</sup>

Photolysis of  $\text{Cp}^*\text{W}(\text{CO})_3\text{Me}$  in the presence of excess  $\text{HSiMe}_2\text{SiMeR}_2$  affords dimeric  $[\text{Cp}^*\text{W}(\text{CO})_2(\text{=SiR}_2)(\text{SiMe}_3)]_2$  (**99**) when  $\text{R} = \text{Me}$ . However, the novel silylene complex,  $\text{Cp}^*\text{W}(\text{CO})_2(\text{=SiR}_2)(\text{SiMe}_3)$  (**100**), is obtained when  $\text{R} = \text{Mes}$ .<sup>186</sup> Kinetic analyses (see *Kinetic Methods*) of hydride abstraction from  $\text{Cp}'\text{W}(\text{CO})_3\text{H}$  using  $[\text{Ph}_3\text{C}]\text{BF}_4$  have revealed that when  $\text{Cp}' = \text{Cp}^*$ , a normal kinetic isotope effect (see *Isotope Effect*) is observed, but when  $\text{Cp}' = \eta^5\text{-C}_5\text{H}_4\text{CO}_2\text{Me}$ , an inverse isotope effect results.<sup>187</sup>

### 3.6 $\eta^6$ -Hydrocarbon Complexes

Surprisingly, little new research on the prototypal tungsten–arene complex (see *Arene Complexes*),  $(\eta^6\text{-C}_6\text{H}_6)_2\text{W}$ , has appeared, possibly because of the low-yielding and elaborate experimental procedures required for its synthesis.<sup>188,189</sup> Photolysis of  $\text{W}(\text{CO})_6$  in the presence of ethyne leads to the formation of benzene and  $(\eta^6\text{-C}_6\text{H}_6)\text{W}(\text{CO})_3$  (**101**),<sup>130</sup> and the solid-state molecular structure of this complex was

only recently reported.<sup>190</sup> Related  $(\eta^6\text{-arene})\text{W}(\text{CO})_3$  complexes catalyze the cyclotrimerization and polymerization of alkynes.<sup>191</sup> Intramolecular (see *Intramolecular*) capture of aryl-containing ligands by an unsaturated metal center also leads to the formation of  $\eta^6$ -arene complexes; for instance, hydrogenolysis of  $[(\text{Me}_3\text{SiN})_2\text{C}_6\text{H}_4](\text{NPh})\text{WR}_2$  ( $\text{R} = \text{CH}_2\text{CH}_2\text{Ph}$ ,  $\text{CH}_2\text{CH}_2\text{CH}_2\text{Ph}$ ) in toluene affords  $[(\text{Me}_3\text{SiN})_2\text{C}_6\text{H}_4](\text{NPh})\text{W}(\eta^6\text{-C}_6\text{H}_5\text{R})$  ( $\text{R} = \text{Et}$ ,  $\text{Pr}^n$ ), and the arene ligands adopt an unusual  $\eta^4$ -coordination mode in the solid state.<sup>192</sup> Furthermore, Na reduction of  $\text{W}(\text{OAr})_2\text{Cl}_4$  ( $\text{Ar} = 2,3,5,6\text{-C}_6\text{HPh}_4$ ) in the presence of a Lewis base generates  $\text{W}(\text{OC}_6\text{HPh}_3\text{-}\eta^6\text{-C}_6\text{H}_5)(\text{OAr})(\text{L})$  (**102**,  $\text{L} = \text{NC}_5\text{H}_4\text{Bu}'$ ),<sup>193</sup> and a closely related complex ( $\text{L} = \text{PMe}_2\text{Ph}$ ) effects an unprecedented 4e reduction of azobenzene at a single metal center.<sup>194</sup>

## Glossary

*Acetogen*: a strictly anaerobic bacterium that produces acetate as the sole fermentation product

*Methanogen*: a strictly anaerobic bacterium that produces methane

*Hyperthermophile*: a microorganism that grows at or above 90 °C

## Abbreviations

FDH = Formate dehydrogenase; CAR = Carboxylic acid reductase; FMDH = Formylmethanofuran dehydrogenase; MFR = Methanofuran; AOR = Aldehyde ferredoxin oxidoreductase; MPT = Molybdopterin; Fd<sub>ox</sub> = Oxidized ferredoxin; Fd<sub>red</sub> = Reduced ferredoxin; FOR = Formaldehyde ferredoxin oxidoreductase; EXAFS = X-ray absorption edge fine structure; kDa = Kilodaltons; EPR = Electron paramagnetic resonance.

## 1 INTRODUCTION

The element Tungsten (W, atomic number 74) has long been prized for its high melting point, good conductivity, and strength. It is used in the manufacture of a wide variety of industrial and household products including light bulb filaments. W is relatively scarce in natural environments, the usual source for this metal being oxo-rich mineral ores such as wolframite ([Fe/Mn]WO<sub>4</sub>, scheelite (CaWO<sub>4</sub>) or the

more reduced form tungstenite (WS<sub>2</sub>)). The concentration of W in soil and freshwater is very low (less than 0.5 nM). In contrast, significantly higher amounts (>50 nM) can be found in alkaline brine lakes, hot springs, and marine hydrothermal vents.<sup>1,2</sup>

Tungsten is a 5d series element and its ionic electronic configuration is [Xe]4f<sup>14</sup>5d<sup>4</sup>6s<sup>2</sup> (see *Tungsten: Inorganic & Coordination Chemistry*). The 4d series element Molybdenum (Mo), situated above W in the periodic table, shares similar chemical properties. The atomic and ionic radii of W and Mo, as well as their electron affinity, are identical. In aqueous solution, both elements are more stable at higher oxidation states and the reduction potentials of their (V/VI) and (IV/V) couples are in the same range, being slightly more negative for W. However, these two analogous elements differ considerably with regard to their role in biology. Molybdoenzymes are ubiquitous in nature and are found in virtually all life forms from microorganisms to eukaryotes (see *Molybdenum: MPT-containing Enzymes*). They play intrinsic roles in the global cycles of nitrogen, carbon, and sulfur metabolism, and their biochemical, structural, and spectroscopic properties have been extensively analyzed.<sup>3,4</sup> In contrast, a functional role for tungsten in biological systems was not realized until the 1970s. Traditionally W had been regarded as an antagonist of the biological function of Mo. Thus microorganisms grown in the presence of W typically try to incorporate W into their molybdoenzymes. This results in the production of either inactive molybdoenzymes lacking any metal or tungsten-substituted molybdoenzymes that have little or no catalytic activity.<sup>5–7</sup> The one notable exception is an enzyme (DMSO reductase) from a photosynthetic bacterium (*Rhodobacter capsulatus*). In this case, the substitution of Mo, the metal that occurs naturally at the active site, by W resulted in an enzyme that retained its three-dimensional structure as well as enzymatic properties.<sup>8</sup> However, this still remains very much an exception and in spite of the high degree of chemical similarity between these two elements, nature is highly selective. Even if tungsten does become incorporated into a molybdoenzyme, its properties are different enough from those of molybdenum to preclude significant catalytic activity.

The first indications that W has a positive role in biology came from reports in the early 1970s when the growth of certain acetate- and methane-producing microorganisms was shown to be stimulated by the addition of tungstate to their growth media.<sup>9</sup> Subsequently, the first naturally occurring tungsten-containing protein was isolated from an acetogen.<sup>10</sup> Since then this field has grown and at present more than a dozen, naturally occurring tungsten-containing enzymes are known. Tungstoenzymes can be found in a variety of microorganisms including those that grow at extreme (hyperthermophiles) as well as conventional temperatures (mesophiles), in archaea and bacteria, and in organisms that reduce sulfur or sulfate, produce methane or acetate, or use acetylene during growth. However, a functional role for W has not been recognized in any eukaryote.

So, what types of organisms have evolved to use tungsten-dependent rather than molybdenum-dependent enzymes, what reactions do these enzymes catalyze, and why is tungsten utilized rather than molybdenum? In the following we address these questions, the answers to which are only just beginning to emerge.

All known tungstoenzymes can be classified into three functionally, phylogenetically, and evolutionarily distinct families. These are: (1) the FMDH family that has two members; formate dehydrogenase (FDH), found in methanogens and acetogens, and N-formylmethanofuran dehydrogenase (FMDH), from methanogenic species; (2) the Aldehyde ferredoxin oxidoreductase (AOR) family, which is represented by the prototypical member, aldehyde ferredoxin oxidoreductase (AOR), and also includes formaldehyde ferredoxin oxidoreductase (FOR), glyceraldehyde-3-phosphate ferredoxin oxidoreductase (GAPOR), the recently identified WOR4 from hyperthermophilic archaea, carboxylic acid reductase (CAR) from acetogens, and aldehyde dehydrogenase (ADH) from sulfate-reducing bacteria; and (3) the acetylene hydratase (AH) family, which has a single member from an acetylene-utilizing bacterium.

## 2 MOLECULAR AND CATALYTIC PROPERTIES OF TUNGSTOENZYMES

### 2.1 F(M)DH Family

It was shown in the mid-1970s that tungstate stimulated the growth of certain acetogenic *Clostridia*, such as *C. thermoaceticum*<sup>11</sup> and *C. formicoaceticum*.<sup>11</sup> These organisms grow by the fermentation of sugars to produce acetate as the sole product. The addition of tungstate to their growth media resulted in a substantial increase in the NADP-dependent formate dehydrogenase activity of cell-free extracts. In addition, the metabolism of formate by the methane-producing organism, *Methanococcus vanniellii*, appeared to be tungsten-dependent.<sup>12</sup> Its growth was stimulated by tungstate when formate was used as the carbon and energy source, but not when the organism was grown on H<sub>2</sub> and CO<sub>2</sub>. Partial purification of the formate dehydrogenase activity of *M. vanniellii* in the early 1980s showed that it contained two types of formate dehydrogenase:<sup>12</sup> one contained molybdenum, while the other seemed to utilize tungsten. The first highly purified form of a tungsten-containing enzyme was reported in 1983 from *C. thermoaceticum*. Its formate dehydrogenase (FDH) contained tungsten, iron and the unusual amino acid selenocysteine, as well as acid-labile sulfur,<sup>10</sup> see Table 1. The tungsten-containing FDHs of methanogens are similarly complex enzymes that contain W, iron–sulfur centers and selenium. Recently two tungsten- and selenium-containing

FDHs were isolated from another type of anaerobic bacterium (*Eubacterium acidaminophilum*).<sup>13</sup> FDHs catalyze the reversible reduction of CO<sub>2</sub> to formate (Table 2), with the concomitant transfer of two electrons from the appropriate electron carrier. This reaction has a very negative reduction potential (−420 mV, SHE). The syntrophic bacterium *Syntrophobacter fumaroxidans* constitutively expressed two W-containing FDH's (FDH-1 and FDH-2) when grown on fumarate or propionate.<sup>14</sup> The purified enzymes exhibit high formate-oxidation and CO<sub>2</sub>-reduction rates and very low K<sub>m</sub> values for formate.

In 1984, a newly isolated methanogen, *Methanobacterium wolfei*, was also shown to require tungsten for growth,<sup>29</sup> although in contrast to *M. vanniellii*, *M. wolfei* grew only on H<sub>2</sub> and CO<sub>2</sub>—it did not utilize formate. A subsequent and extensive survey<sup>30</sup> of the incorporation of radiolabeled tungstate (<sup>185</sup>W) into methanogenic species showed that several accumulated significant amounts of the element into their protein fractions. An additional role for tungsten in some methanogens, however, remained unknown until the discovery of the enzyme FMDH. FMDH is found only in the methanogens where it catalyzes the reduction and addition of CO<sub>2</sub> to the organic, methanogenic cofactor, methanofuran (Table 2). The physiological electron donor for this reaction is not known. Methanogens grow on H<sub>2</sub> and CO<sub>2</sub> and generate methane. FMDH catalyzes the first step in the conversion of CO<sub>2</sub> to methane. FMDHs are complex multisubunit enzymes (Table 1) that are intrinsically labile and extremely oxygen sensitive. Usually these enzymes have a Mo cofactor, however, in several thermophilic and hyperthermophilic methanogens, the enzyme contains W.

### 2.2 AOR Family

The AOR family has been the most extensively studied and the majority of tungstoenzymes known at present belong to this family.<sup>2,31</sup> AOR was first isolated from the hyperthermophilic archaeon *Pyrococcus furiosus*.<sup>15,16</sup> Subsequently, three other members of this family FOR, GAPOR, and WOR4 were purified and characterized from *P. furiosus*.<sup>17,19,21</sup> All four enzymes consist of a single type of subunit of ~70 Kilodaltons (kDa) in size, but they differ in their quaternary structures (Table 1). Whereas GAPOR is monomeric, AOR and WOR4 are dimeric and FOR is a tetramer. Each of their subunits contains a mononuclear W site and one iron–sulfur cluster (see **Iron–Sulfur Proteins**). A comparison of their complete amino acid sequences show that AOR, FOR, and WOR4 are most closely related (40% sequence identity with each other) while GAPOR is more distant (23% identity).<sup>21</sup> AOR, FOR, and GAPOR catalyze the conversion of various types of aldehyde to the corresponding acid (Table 2). The reaction involves two-electron oxidation and *in vivo* ferredoxin serves as the electron acceptor. In contrast to other members of the family *P. furiosus* WOR4 does not appear to oxidize

**Table 1** Molecular properties of tungsten-containing enzymes

| Organism/enzyme <sup>a</sup> | Holoenzyme M <sub>r</sub> (kDa) | Subunits/M <sub>r</sub> (kDa)     | W content <sup>b</sup> | FeS or cluster content <sup>c</sup>      | Pterin cofactor <sup>d</sup> |

aldehydes or 2-hydroxyacids or catalyze the reverse reaction of acid reduction.<sup>21</sup>

CAR was discovered in acetate-producing bacteria based on its ability to catalyze the reverse reaction, the reductive activation of carboxylic acids, though it can also catalyze aldehyde oxidation (Table 2). The acid/aldehyde couple has an extremely low reduction potential, for example, E<sub>0'</sub> value for acetaldehyde/acetate is –580 mV (SHE) and therefore, aldehyde oxidation is much more thermodynamically favorable than acid reduction. The electron carrier for the enzyme inside the cell is not known. CAR isolated from *C. formicoaceticum* has molecular

properties very similar to that of *P. furiosus* AOR whereas CAR from *C. thermoacetikum* has a more complex organization<sup>22</sup> (Table 1). The final member of this family is ADH from sulfate-reducing bacteria.<sup>24</sup> Its molecular properties closely resemble those of AOR (Table 1).

### 2.3 Acetylene Hydratase

This family is represented by just one member, AH from the acetylene-utilizing anaerobic bacterium, *Pelobacter acetylenicus*.<sup>27</sup> It comprises a single type of subunit that contains one W and a single iron–sulfur cluster (Table 1).

In contrast to reactions catalyzed by other tungstoenzymes, this enzyme does not appear to catalyze an overall oxidation or reduction. AH catalyzed the hydration of acetylene to acetaldehyde (Table 2). However, AH was found to be active only in the presence of a strong reducing agent, therefore, acetylene hydration might involve consecutive reduction, hydration, and oxidation steps, wherein the W site and the FeS center are required to carry out the redox chemistry. When *P. acetylenicus* was grown in the presence of Mo a fully functional Mo-containing AH was obtained, suggesting that W is not essential for the catalysis of acetylene hydration.<sup>27</sup>

### 3 PHYSIOLOGICAL ROLES

Most tungstoenzymes isolated so far have been from obligate anaerobes that are also thermophilic to a greater or lesser extent. Moreover, the enzymes have similar catalytic properties. They all catalyze a redox reaction involving conversions at the level of carboxylic acids and aldehydes (with the exception of AH). However, their physiological roles are distinctly different.

FMDH is found only in methane-producing organisms and catalyzes the first step in the conversion of CO<sub>2</sub> to methane. Using methanofuran as the C-1 carrier, FMDH catalyzes the reduction of CO<sub>2</sub> to N-formylmethanofuran. The formyl group is then reduced by a complex series of enzymes and novel cofactors to methane. FMDH is a molybdoenzyme in almost all methanogens so far examined. The notable exception is the moderate thermophile, *M. wolfei*, which grows optimally at 65 °C, in which the enzyme contains tungsten.<sup>26</sup> In fact, this organism contains two FMDHs: one (FMDH II) contains tungsten while the other (FMDH I) contains molybdenum.<sup>32</sup> The latter has also been purified as a catalytically active, 'tungsten-substituted molybdoenzyme' from cells grown in the absence of molybdenum and presence of tungsten.

Like methanogens, the acetogenic clostridia also grow on H<sub>2</sub> and CO<sub>2</sub> (as well as on sugars) but in these organisms CO<sub>2</sub> is ultimately reduced to acetate rather than methane. The first step in the conversion of CO<sub>2</sub> to the methyl group of acetate is catalyzed by FDH. This generates formate, which is subsequently activated and reduced by a series of enzymes using tetrahydrofolate as the C-1 carrier.<sup>33</sup> Acetogens vary in their responses to the addition of tungsten and molybdenum to their growth media, and in some species FDH appears to contain molybdenum while in others FDH seems to be dependent upon tungsten.<sup>34,35</sup> Tungsten-containing FDHs have been purified from the moderate thermophile *C. thermoaceticum*, which grows optimally near 60 °C, and from the mesophile *C. formicoaceticum*.<sup>35</sup> The effects of these two elements on the growth of acetogens is complicated by the finding, in at least some of these organisms, of a second tungstoenzyme, CAR, which reduces carboxylic acids. So far CAR has been purified from

the same two acetogens as FDH, *C. thermoaceticum* and *C. formicoaceticum*.<sup>22,36</sup> In fact, *C. formicoaceticum* has been shown to produce two distinct CARs, one containing molybdenum and one containing tungsten.<sup>23</sup> Neither the role of CAR nor its physiological electron carrier are known.<sup>37</sup> This is in spite of the fact that CAR represents about 4% of the total cytoplasmic protein in *C. formicoaceticum*.

It is now evident that tungsten has as at least four different physiological roles in hyperthermophilic microorganisms. In the saccharolytic fermenters such as *P. furiosus*, tungsten-containing GAPOR is known to catalyze a key step in the unusual glycolytic pathway that this microorganism uses to convert glucose to pyruvate.<sup>19,20</sup> GAPOR is absolutely specific for glyceraldehyde-3-phosphate, which is oxidized to 3-phosphoglycerate. Under proteolytic growth conditions of *P. furiosus* or *T. litoralis*, AOR is thought to play a role in the degradation of amino acids.<sup>38</sup> The enzyme shows the highest catalytic efficiencies (and low K<sub>m</sub> values) with acetaldehyde (from alanine), isovaleraldehyde (from valine), indoleacetaldehyde (from tryptophan), and phenylacetaldehyde (from phenylalanine). These aldehydes are derived by the transamination (conversion of an amino acid to a keto acid) and decarboxylation (conversion of a keto acid to an aldehyde) of the common amino acids alanine, valine, tryptophan, and phenylalanine, respectively. A third role for tungstoenzymes comes in the form of FOR, which also appears to be involved in the breakdown of amino acids by *P. furiosus*.<sup>17</sup> Originally isolated based on its ability to oxidize formaldehyde, FOR can also use other short-chain (C<sub>1</sub>–C<sub>4</sub>) aldehydes as substrates. However, the K<sub>m</sub> values for such substrates are very high (>10 mM), especially for formaldehyde (25 mM), indicating that these are unlikely to be physiological substrates (Table 2). The lack of significant activity with longer chain aldehydes (≥C-5) or with aromatic aldehydes indicates that the catalytic site of FOR is probably accessible to only short-chain aldehydes. Interestingly, this tungstoenzyme shows high activity (and low K<sub>m</sub> values) with C<sub>4</sub>–C<sub>6</sub> di- and semialdehydes. Such compounds are intermediates in the metabolic pathways of amino acids such as arginine, lysine, and proline. Since the organisms in which FOR has been found, such as *P. furiosus* and *T. litoralis*, grow using proteins as a primary carbon source, FOR may well have a role in amino acid metabolism, although this has yet to be established.<sup>17</sup> Neither GAPOR, FOR, nor AOR can utilize the nicotinamide nucleotides, NAD and NADP, as electron carriers. Instead, these enzymes couple substrate oxidation to the reduction of the extremely thermostable redox protein, ferredoxin. Excess reductant generated from the fermentative metabolism is then disposed of as H<sub>2</sub> by a thermostable hydrogenase which uses reduced ferredoxin as the electron donor.<sup>39</sup> Despite sharing high homology with AOR the fourth tungstoenzyme isolated from *P. furiosus* WOR4<sup>21</sup> does not appear to catalyze aldehyde oxidation or acid reduction. In fact, the reaction catalyzed by this novel enzyme, the fourth for a

**Figure 1** Structure of pterin cofactor found in tungstoenzymes such as *P. furiosus* AOR

**Figure 2** Ball-and-stick representation of the pterin cofactor and the adjacent [4Fe-4S] cluster in *P. furiosus* AOR. The side chain of a Cys residue that coordinates the cluster and hydrogen bonds with an N atom of the pterin cofactor is indicated<sup>40</sup>

tungstoenzyme in this organism, and thereby its physiological role, remains unknown.

#### 4 STRUCTURAL PROPERTIES OF TUNGSTOENZYMES

The W atom in tungstoenzymes is coordinated by the same cofactor that coordinates the Mo in molybdoenzymes: An organic moiety known as the pterin cofactor that is based on the two-ring pteridine nucleus that is present in the vitamin folic acid (Figure 1; see **Molybdenum: MPT-containing Enzymes**). The crystal structure of *P. furiosus* AOR was the first for a tungsten-containing protein and for a pterin-containing protein (and the first for an enzyme from an organism that can grow at 100 °C).<sup>16</sup> Interestingly, the structure revealed that the cofactor in the W-enzymes is a *three-ring* system. The third ring contains a dithiolene group, where the two sulfur atoms coordinate the W atom (Figure 2). Subsequent structural analyses of molybdoenzymes have

shown that the pterin cofactor in the two types of enzyme are the same. Analyses of the cofactor from the protein indicated that in molybdoenzymes from bacteria the pterin is usually modified with a mononucleotide (AMP, GMP, CMP, or IMP) attached to a terminal phosphate, which is typically lacking in Mo-enzymes from higher organisms. Such an appended nucleotide is also absent in the members of the AOR family of tungstoenzymes (Table 1) but the dinucleotide form of the cofactor is present in FMDH and FDH.

*P. furiosus* AOR is a homodimer in which each subunit contains an iron-sulfur cluster and coordinates a single mononuclear Fe site at the dimer interface. The W atom in AOR was found to be coordinated not by two S atoms from one pterin cofactor, but by four S of the dithiolene side chains from two pterins (Figure 2). The geometry of the W site in the enzyme displays a distorted square pyramidal arrangement, with an angle of 97° between the planes of the pterin ligands. The pterins are linked to each other through their phosphate groups, which coordinate the same Mg<sup>2+</sup> ion. The W atom is buried deep inside the protein approximately 10 Å away from the iron-sulfur cluster (Figure 2). A hydrophobic channel leads from the W site to the surface of the protein. This channel is lined with apolar residues and is large enough to accommodate even aromatic substrates, consistent with the ability of AOR to oxidize a broad range of substrates. The iron-sulfur cluster is located close to the protein surface consistent with its role as an intermediary electron carrier between the W atom and the redox protein ferredoxin. The cluster is coordinated by the protein via four cysteine ligands. One of these Cys is positioned to accept a hydrogen bond from a pterin ring nitrogen, hinting at pterin's role as an active participant in the redox chemistry of the enzyme (Figure 2).

The crystal structure of FOR from *P. furiosus* has been solved at 1.8 Å resolution.<sup>18</sup> The overall folding of the FOR subunit is very similar to that of AOR, consistent with their high sequence similarity. However, FOR is a homotetramer with the four subunits arranged around a central cavity approximately 27 Å in diameter. Like AOR, each subunit of FOR comprises an iron-sulfur cluster and one W atom coordinated to a bis-pterin cofactor. FOR does have an additional metal site, a Ca ion situated close to one of the pterin cofactors, but it appears to play a purely structural role (see **Calcium-binding Proteins**). The active site cavity in FOR has two distinctive parts: a large chamber at the bottom and a much narrower channel leading toward the protein surface. The bottom chamber that contains the tungstopterite site is lined with amino acids with bulky side chains. Consequently, the active site cavity in FOR is much smaller than that in AOR, and these variations contribute to the differences in substrate specificity between these two enzymes. Although the structures of the other tungstoenzymes from *P. furiosus*, GAPOR and WOR4, is not known, their amino acid sequence, size, and W and Fe contents suggest that these enzymes are probably closely related in structure to AOR and FOR. The molecular properties of *C. formicoaceticum* CAR are similar

to those of *P. furiosus* AOR, although its larger counterpart isolated from *C. thermoaceticum* contains additional subunits, FAD and a much higher Fe content (Table 1). The same is probably true for ADH, whose quaternary structure, subunit size, and W and Fe contents also match those of *P. furiosus* AOR (Table 1).

Structures have yet to be reported for the FDH and FMDH class of tungstoenzyme. However, the structure of the Mo-containing FDH<sub>H</sub> from *E. coli*,<sup>25</sup> which shows 20% similarity in its amino acid sequence to that of the catalytic subunit of *Methanopyrus kandleri* FMDH, has recently been elucidated. FDH<sub>H</sub> is a component of the anaerobic formate hydrogen lyase complex and is a monomer of 79 kDa. It contains an iron–sulfur cluster and one Mo atom coordinated by a bis-pterin-MGD cofactor and the selenium atom of a selenocysteine residue (see **Selenium Proteins Containing Selenocysteine**). The coordination geometry of Mo in the reduced enzyme is square pyramidal where the four sulfur atoms form the equilateral ligands and the Se site is at the axial position. Sequence comparisons suggest that W-containing FMDH may have a similar active site, especially since FMDHs of some methanogens also appear to contain selenium.

## 5 SPECTROSCOPIC PROPERTIES

By analogy with the redox behavior of molybdenum in molybdoenzymes (see **Molybdenum: MPT-containing Enzymes**), a monomeric tungsten site in a tungstoenzyme could be reasonably expected to exist in oxidized (W(VI)), intermediate (W(V)), and reduced (W(IV)) states, where only the intermediate state is paramagnetic and thus Electron paramagnetic resonance (EPR) active. In recent years, the tungstoenzymes listed in Table 1 have been subjected to detailed studies using electron paramagnetic resonance (EPR), X-ray absorption (XAS), resonance Raman, and variable temperature magnetic circular dichroism (MCD) spectroscopies, in an effort to investigate their structure and mechanism. The reduced form of *P. furiosus* AOR is red in color and exhibits broad visible absorption peaks near 400 and 540 nm. When oxidized either by exposure to air or by treatment with ferricyanide, the protein turns a greenish-brown color and the absorption at 400 nm increases by about two-fold. This increase in visible absorption is characteristic of the Fe–S chromophore (see **Iron–Sulfur Proteins**). FOR, GAPOR, ADH, and CAR all exhibit similar absorption spectra in their oxidized and reduced forms. Any contribution of the tungstopterin cofactor to the visible spectrum in these enzymes is probably masked by the broad peak from their Fe–S cluster.

During catalysis the W center is thought to undergo a two-electron cycle between the (IV)/(V)/(VI) oxidation states. W(V) has a  $d^1$ -configuration, is paramagnetic and exhibits electron paramagnetic resonance (EPR) signals with  $g$ -values less than 2. These signals are typically slow-relaxing

and observable at temperatures above 100 K. W(IV) and W(VI), on the other hand, are diamagnetic and do not display EPR signals. Enzymes from all three classes of tungstoenzyme, AOR, FM(D)H, and AH, show resonances attributed to W(V) species.<sup>31</sup> The spectra are assigned to W(V) based on their relaxation properties and  $g$ -values. Unambiguous identification of the resonances come from hyperfine interactions arising from <sup>183</sup>W, which has a nuclear spin  $I = 1/2$ . The enriched enzymes are obtained from cells grown in the presence of <sup>183</sup>W-tungstate.<sup>31</sup>

Extensive EPR studies of AOR and FOR from *P. furiosus* show that the W site in these enzymes is not homogeneous. As many as four distinct W species are present and each has a distinctive W(V) EPR signal.<sup>41,42</sup> For example, the catalytically active form of the W site is thought to represent less than 50% of the total, and this gives rise to a ‘low-potential’ magnetically isolated W(V) species, that cycles between the W(IV)/W(V)/W(VI) states at physiologically relevant potentials (–450 mV to –250 mV at 25 °C). The signal has a rhombic lineshape with  $g$ -values, which are directly related to the electronic properties of the W atom, of 1.98, 1.90, 1.85. This low-potential signal is observed in all active AOR and FOR samples. A further 30% of the total W gives rise to a ‘high-potential’ W(V) signal at potentials (>0 mV) that are considered not to be physiologically relevant. The presence of up to four different W species in the same sample, representing active and inactive forms of these enzyme, explains the ambiguity observed in conclusively identifying the ligands to the W atom by crystallographic analyses.<sup>16,18</sup> The W centers of ADH and CAR also give rise to multiple EPR signals.<sup>11</sup> The source of the heterogeneity at the active center of members of the AOR group of tungstoenzymes is not clear.

The [4Fe–4S] cluster in AOR and FOR is paramagnetic in its reduced form and displays characteristic EPR resonances, although the spin relaxation rate is very fast and the spectra are observed only at very low temperatures (see **Iron–Sulfur Proteins**). Hence, at 4 K, the EPR spectrum of AOR is dominated by resonances from its reduced Fe–S cluster. However, this gives rise to a rhombic signal from a  $S = 3/2$  ground state, while reduced 4Fe-clusters typically have an  $S = 1/2$  ground state. In fact, while mixed spin,  $S = 3/2$  and  $S = 1/2$  reduced [4Fe–4S] clusters are sometimes observed in some iron–sulfur proteins (see **Iron–Sulfur Proteins**), clusters that have exclusively  $S = 3/2$  ground states are so far unique to AOR.<sup>41</sup> Indeed, the reduced 4Fe-cluster of FOR has a mixed spin state with  $S = 3/2$  (80%) and  $S = 1/2$  (20%) components. The factors that determine the spin state of a [4Fe–4S] center have yet to be elucidated.

FDH provided the first example of W(V) EPR resonances from a biological system.<sup>43</sup> At lower temperatures, resonances are seen from reduced iron–sulfur centers (both [2Fe–2S] and [4Fe–4S]), whereas at higher temperatures the reduced enzyme exhibits a slow-relaxing signal with unusually high  $g$ -values ( $g = 2.1, 1.98, 1.95$ ). These anomalous EPR properties

have been attributed to the S-rich environment of the W comprising four S from two dithiolene side chains, a coordinated selenocysteine and the lack of an oxo ligand in the W(V) state.<sup>31</sup> On the other hand, simple rhombic-type EPR spectra from a W(V) site were reported in the mid 70s from catalytically inactive, tungsten-substituted sulfite oxidase,<sup>44</sup> and more recently from the catalytically active, tungsten-substituted form of *M. wolfei* FMDH I. The latter enzyme in its air-oxidized form exhibited a rhombic EPR signal ( $g_z = 2.049$ ,  $g_y = 2.012$ ,  $g_x = 1.963$ ) from the W(V) site and this had the expected isotope splitting ( $^{183}\text{W}$ , 14.4%,  $I = 1/2$ ). Since this enzyme is rapidly inactivated in air, the catalytic significance of the air-oxidized form is not known, although the results suggest that the active enzyme as isolated under reducing conditions contains a reduced W(IV) center. The EPR properties of FMDH have not been reported but the sole member of the third class of tungstoenzyme, AH, also gives rise to a slow-relaxing EPR signal with relatively high  $g$ -values ( $g = 2.04$ , 2.02, 2.00) that is assigned to W(V).<sup>28</sup> These properties suggest that the enzyme contains a W site coordinated by the S atoms of two pterins and possibly a cysteine ligand. Unfortunately the latter cannot be substantiated by sequence comparisons with F(M)DH and the FDH family of molybdoenzymes. Tungstoenzymes can therefore be classified into two distinct groups based on their EPR properties. In the AOR class, the active site W is coordinated by the dithiolene side chains from two nonnucleotide pterin cofactors and an oxo (or possibly an hydroxyl) ligand in the W(V) state, but there is no direct interaction with any protein side chain. AOR, FOR, GAPOR, ADH, and CAR all appear to fit in this group, despite considerable heterogeneity of their active sites by EPR analyses. In contrast, it appears that the FM(D)H class contain a W center coordinated by the nucleotide form of pterin cofactor with an additional cysteine or selenocysteine ligand from the protein. The latter property leads to an increase in the  $g_{av}$  value of the W(V) EPR signal. This second category may also include AH.

## 6 EVOLUTIONARY CONSIDERATIONS

The tungstoenzymes known so far (Table 1) all catalyze reactions of very low potential ( $\leq -420$  mV) and have been found only in strictly anaerobic organisms, the majority of which grow at moderate or extreme temperatures. The moderately thermophilic organisms appear not to be obligately dependent upon tungsten for growth as analogous molybdoenzymes seem to be synthesized if tungsten is omitted and molybdenum is added to the culture medium. Whether the hyperthermophiles are the first organisms to absolutely require tungsten for growth remains to be established. Nevertheless, tungstoenzymes appear to play key roles in the primary metabolic pathways for the catabolism of both carbohydrates

and peptides in the hyperthermophiles. If one compares the properties of the mononuclear W and Mo synthetic complexes,<sup>6,45</sup> it is evident that the relevant W complexes are much more oxygen sensitive than the equivalent Mo compounds, indicating that such a W site within an enzyme would be active only under anaerobic conditions. Similarly, the W complexes display enhanced thermal stability compared to Mo complexes, suggesting that the former rather than the latter would be preferred at temperatures near the normal boiling point. This enhanced bond strength of W complexes may also account for the observation that such complexes are generally kinetically slower than the equivalent Mo complexes. In addition, the much lower redox potentials (typically by more than 300 mV) for the W complexes compared to the Mo ones indicate W is better suited to catalyze lower potential redox processes.<sup>6</sup> Lastly, availability of these metals may play a major role in which of these metals is utilized in different ecosystems. For example, in freshwater and marine environments the concentration of W is typically several orders of magnitude lower than Mo, although in deep-sea hydrothermal vent systems W is much more prevalent than Mo.<sup>2</sup> Hence, it might be expected that W would only be utilized in biological systems to catalyze low-potential reactions under anaerobic conditions, and that significant catalytic rates would be observed only at high temperatures. Conversely, Mo complexes would be unstable at high temperatures but at lower temperatures they would be catalytically competent over the whole biological range of potentials under both aerobic and anaerobic conditions.<sup>6</sup> In fact, most of the W-utilizing microorganisms produce functional Mo-containing isoforms of their tungstoenzymes when they are grown in the presence of Mo rather than W. For example, functional Mo-containing isoenzymes exist for W-containing FMDH, CAR, FDH, and AH in their respective mesophilic or thermophilic organism.<sup>31</sup> The notable exception is the AOR family of tungstoenzymes found in hyperthermophiles such as *P. furiosus*.<sup>2,31</sup> So far they are the only known organisms that obligately require W for growth. They do not contain Mo-analogs of the AOR family, and they appear not to utilize Mo. Such organisms carry out chemical reactions near the limits of biology, at extremely low potentials and at high temperatures. It is possible that catalysis under such extreme conditions is a feat that can be accomplished by W but not by Mo. As yet, a Mo-containing enzyme has not been isolated from an organism that can grow at the normal boiling point.

## 1 INTRODUCTION

It is now well established that the element vanadium, which is universally distributed in the soil,<sup>1</sup> plays a role in biological systems. This metal is essential for the functioning of the bacterial nitrogen fixation system (*see Nitrogenase Catalysis & Assembly*) and vanadate is the prosthetic group in the vanadium haloperoxidases from seaweeds and dematiaceous hyphomycetes. As a result, the chemistry of model compounds<sup>2,3</sup> for these biomolecules has been investigated in detail. Furthermore, some vanadium compounds mimic most of the metabolic effects of insulin and the number of publications dealing with the subject has increased exponentially. Four books<sup>4-7</sup> and a large number of reviews<sup>8-10</sup> have appeared which cover several aspects such as the role of the metal in the biosphere, the inorganic and redox chemistry of vanadium, and the insulin mimetic effect of vanadate. An international symposium on chemistry and biological chemistry of vanadium is also organized regularly. In this chapter, the role of the metal in vanadium haloperoxidases will be discussed and the status of the high concentration of vanadium in fan worms and its possible role in the blood cells of Ascidians will be reviewed. It is clear that the field of vanadium biochemistry has rapidly developed and further discoveries and surprises are expected.

Vanadium has 4 oxidation states of which only vanadium<sup>III,IV</sup> and V occur in biological systems. Vanadium<sup>V</sup>

and IV are the most common and vanadium<sup>III</sup> has been detected only in tunicates and fan worms.<sup>11</sup> At neutral pH, vanadium is mostly found as vanadate and depending upon pH and concentration, vanadate oligomers including the dimer, tetramer, and decamer forms are found. At low concentrations such as in seawater,<sup>12</sup> only the monomeric species will be present, probably in the diprotonated state. Vanadate, by virtue of being a structural analogue of phosphate, has inhibitory, stimulatory, and regulatory effects on biochemical processes that in a number of cases are due to the formation of enzyme-vanadate intermediates.<sup>9</sup> Vanadate is easily reduced to the IV state by common reducing agents under physiological conditions. In aqueous solutions, most of the reduced vanadium species found exists as vanadyl (VO<sup>2+</sup>), which forms strong complexes with a great variety of ligands including proteins (*see Vanadium: Inorganic & Coordination Chemistry*). At neutral pH values the vanadyl species are easily oxidized by air to vanadium<sup>V</sup>. As a d<sup>1</sup> metal ion, vanadium<sup>IV</sup> has one unpaired electron which is strongly coupled to the <sup>51</sup>V nucleus (I = 7/2) giving rise to either 8 or 2 sets of 8 overlapping lines in axial symmetric complexes. This typical signal is easily detectable and it is possible by the EPR technique (*see Electron Paramagnetic Resonance*) to observe relatively low concentrations of the metal.

## 2 VANADIUM BROMOPEROXIDASES

### 2.1 Occurrence

A striking array of halogenated products produced by natural sources is found in the biosphere. The majority are probably formed by the enzymatic activity of haloperoxidases.<sup>13</sup> The detailed mechanism by which haloperoxidases catalyze the insertions of a halogen into organic molecules is still a point of debate. However, for most of these enzymes a simple reaction mechanism has been observed that consists of a two-electron oxidation of the electron donor (Cl<sup>-</sup>, Br<sup>-</sup>, I<sup>-</sup>) by H<sub>2</sub>O<sub>2</sub> to hypohalous acids (equation 1):

By definition enzymes that are able to oxidize chloride, bromide, and iodide are called chloroperoxidases and those able to oxidize bromide and iodide, bromoperoxidases. If a nucleophilic acceptor (RH) is present, a reaction will occur with HOX and halogenated compounds (*see Halocarbons & Halocarbon Complexes*) are produced (equation 2).

HOX will react with a broad range of acceptors (RH) to form a diversity of halogenated reaction products (RX). As we know now, most of the marine haloperoxidases contain

vanadate in the active site.<sup>14,15</sup> These enzymes, which have been detected in a great variety of brown and red seaweed samples, are widespread in the marine environment and have been found in seaweeds from the Great Barrier Reef in Australia, the Sea of Japan, the East Pacific, and the North Atlantic Ocean. Vanadium iodoperoxidases have also been identified in some brown seaweeds but they have hardly been studied. Also diatoms have been reported to contain haloperoxidases. The vanadium peroxidases are probably also responsible for the formation of huge amounts of bromoform by seaweeds and phytoplankton. Some oceans are even saturated with this compound with the result that ventilation to the atmosphere occurs and this volatile organohalogen participates in chemical processes in the atmosphere.<sup>13</sup> The biological function of the formation of bromoform by these algae is not clear. Some of the organohalogens formed and also HOBr have biocidal effects and prevent biofilm formation by bacteria on the surface of seaweeds. It is likely that formation of these compounds is part of a host defense system.<sup>13</sup>

## 2.2 Catalytic Properties

The vanadium peroxidases differ from the heme-containing peroxidases (*see Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases*) in their specificity for halides. The vanadium enzymes do not oxidize classical organic electron donors such as guaiacol, *o*-dianisidine, and benzidine. Thus assay systems used are those that detect the formation of HOCl, HOBr, or HOI. Routinely, the halogenating activity of these enzymes is determined by measuring the bromination or chlorination of the cyclic diketone monochlorodimedon to the dihalogenated compound. At more alkaline pH values and in particular at high concentrations of H<sub>2</sub>O<sub>2</sub>, a competing reaction (equation 3) between H<sub>2</sub>O<sub>2</sub> and HOX occurs. This results in singlet oxygen formation and an apparent decrease in the rate of bromination or chlorination of monochlorodimedon.

Therefore it is also possible to measure enzyme activity without a HOX scavenger by monitoring the rate of dioxygen formation directly using an oxygen electrode.<sup>16</sup> This is at high pH a more accurate measure of bromoperoxidase activity. <sup>1</sup>O<sub>2</sub> production can also be measured at 1268 nm (*see Dioxygen & Related Ligands*).<sup>17</sup> A convenient qualitative method to assay the haloperoxidase activity is following the bromination of phenol red to bromophenol blue; this results in a marked color change taking place which allows screening of haloperoxidase activity of large numbers of samples by simple visual inspection.<sup>18</sup> The turnover values of the bromoperoxidases vary considerably among the various seaweed species. Extensive steady-state kinetic studies have been carried out that show that hydrogen peroxide and bromide (as a substrate) react with the enzyme in a sequential order and the kinetic mechanisms for the bromoperoxidases from various sources

are all very similar.<sup>10</sup> Slight inhibition of bromoperoxidase by high concentrations of H<sub>2</sub>O<sub>2</sub> (120–400 mM) with stronger inhibition at higher pH has been observed. Interestingly, the *K<sub>M</sub>* value for H<sub>2</sub>O<sub>2</sub> increases with increasing proton concentration. This appears to be due to protonation of a group with a *pK<sub>a</sub>* of 5.7–6.7 that upon protonation prevents binding of peroxide. In contrast the *K<sub>M</sub>* for bromide is hardly affected by pH.

On the basis of kinetic studies the presence of a peroxo-intermediate was postulated and spectroscopic evidence for such an intermediate has been obtained.<sup>10,19</sup> Br<sub>3</sub><sup>−</sup>, Br<sub>2</sub>, or HOBr appear to be the primary reaction products of the enzyme-mediated peroxidation of bromide.<sup>19</sup> The vanadium enzyme also uses phenylperacetic acid, *m*-chloroperoxybenzoic acid, and *p*-nitroperoxybenzoic acid as oxidants, but alkyl peroxides such as ethylhydroperoxide, tert-butyl hydroperoxide, and cuminyl hydroperoxide are not substrates for the enzyme in the oxidation of bromide.<sup>20</sup> The enzyme from the brown seaweed *Ascophyllum nodosum* does not display any specificity with regard to bromination of various organic nucleophilic acceptors which suggests a mechanism in which the oxidized bromine species are released into solution by the enzyme.<sup>21</sup> Figure 1 gives a simple model for the reaction mechanism of the enzyme.

However, it is clear that during catalysis an enzyme-bound bromonium intermediate is formed which binds specifically indoles and catalyzes a regio-selective bromoperoxidative oxidation.<sup>22</sup> This brown seaweed produces highly volatile and simple halohydrocarbons such as CH<sub>2</sub>Br<sub>2</sub> and CH<sub>3</sub>Br. These halohydrocarbons are formed by reaction of enzymatically generated HOBr with organic matter that slowly decays to form these halohydrocarbons.<sup>13,23</sup> Thus the reported oxidation of indoles<sup>22</sup> is most probably not related to the known physiological role of the enzyme.

## 2.3 Nature of the Active Site

Vanadium bromoperoxidases lose their enzymic activity at low pH in buffers containing phosphate and EDTA. Also during purification procedures, the enzyme slowly

**Figure 1** Simplified model for the reaction mechanism of the vanadium bromoperoxidases. As we will see later this mechanism may be slightly different for the vanadium chloroperoxidases

inactivates if phosphate buffers are used.<sup>10</sup> However, in the absence of phosphate-containing buffers, the enzyme retains its activity for months.<sup>10</sup> To inactivate the enzyme completely the presence of phosphate in the procedure is essential.<sup>14</sup> Incubation of the apoenzyme at neutral pH with orthovanadate ( $\text{VO}_4^{3-}$ , which is the vanadium<sup>V</sup>oxy-anion) results in recovery of the enzymatic activity as discovered originally by Vilter.<sup>14</sup> Reconstitution is inhibited competitively by structural analogs such as phosphate ( $\text{PO}_4^{3-}$ ), arsenate ( $\text{AsO}_4^{3-}$ ), molybdate ( $\text{MoO}_4^{2-}$ ), fluoroberyllate, and fluoroaluminate.<sup>10</sup> The reconstitution of the apoenzyme by vanadate suggests that vanadate is present in the active site. The X-ray structures show that vanadate is indeed the prosthetic group in these enzymes.<sup>24</sup> The affinity of the apobromoperoxidase for vanadate is quite high. Values of 35–55 nM have been reported<sup>10,14</sup> that are close to the concentration of vanadate in seawater of 35 nM<sup>12</sup> suggesting that for incorporation of vanadate into the apoenzyme, *in vivo*, no additional enzyme system is required.

Since the enzyme is nearly colorless and displays only a weak band around 315 nm in the optical absorption spectrum,<sup>10</sup> it is difficult to gain information by optical spectroscopy. EPR, Electron Spin Echo Envelope Modulation Spectroscopy (ESEEM), X-ray spectroscopy, and <sup>51</sup>V NMR have been used to probe the nature of the active site in these peroxidases. EPR studies on the bromoperoxidase from the brown seaweed *A. nodosum* have shown that the oxidation state of the metal in the native form is vanadium<sup>V</sup> and that its redox state does not change during turnover.<sup>25,26</sup> The role of the vanadium<sup>V</sup> in the enzyme is probably to coordinate and to activate hydrogen peroxide resulting in reaction of the halide with this activated peroxide to yield hypohalous acid. Owing to its low radius/charge ratio vanadium may act as a Lewis acid in which the metal effectively withdraws electron density from the bound peroxide in such a way that the halide is able to react with this activated peroxide intermediate of the enzyme to yield hypohalous acid. In this mechanism, no redox changes occur in the vanadium metal center. These spectroscopic methods have not only yielded insight into the mechanism but structural data have also been obtained. For example, based on the results of EXAFS studies the conclusion was reached that the geometry of the metal oxide bound in the active site was five-coordinate.<sup>27</sup> EPR and ESEEM studies on the reduced enzyme demonstrated clearly that water is in the direct coordination sphere of the metal oxide.<sup>25,26</sup> The EXAFS data showed the presence of multiple scattering effects from outer atoms of a group corresponding to a histidine ligated to vanadium. Also the ESEEM experiments<sup>26</sup> clearly indicated the presence of a histidine residue in the active site as confirmed now by the X-ray structure of the vanadium bromoperoxidase from *Ascophyllum nodosum*.<sup>24</sup>

## 2.4 X-ray Structures of Vanadium Bromoperoxidases

The homo-dimeric structure of the enzyme from *A. nodosum* consists of 1111 amino acids with a calculated

**Figure 2** Ribbon type representation of the vanadium bromoperoxidase dimer from *A. nodosum*. The  $\alpha$  helices on the top are linked together by two disulfide bridges. (Reprinted from Ref. 24, © 1999, with permission from Elsevier)

molecular mass of 120 kDa.<sup>24</sup> The primary sequence was determined by combining the results of DNA sequencing, protein sequencing, and electron density interpretation. The dimeric enzyme is a compact ellipsoid of approximately 90 Å in length and with a diameter of about 76 Å (Figure 2). The monomer of the enzyme consists of a predominantly helical secondary structure, being composed of 18  $\alpha$ -helices and eight short  $\beta$ -strands. Two four-helix bundles and six long helices (each monomer donating a four-helix bundle and three long helices) form the highly rigid and compact core of the dimeric structure. This includes the two vanadium active sites, which reside at the N-terminal end of one of the four helices of each monomer. The monomers are linked covalently in the N-terminal region by two disulfide bridges, four well-defined salt bridges and a large number of hydrogen bonds involving both side-chain and main-chain residues. The two long helices at the N-terminus in each monomer are aligned antiparallel with respect to each other. Additionally, each monomer has three intramolecular disulfide bridges. Thus each dimer contains eight disulfide bridges in line with previous estimates.<sup>10</sup>

Vanadate is bound on the N-terminal side of a four-helix bundle and the vanadium metal is the center of a trigonal bipyramid with three oxygen atoms coordinated in the equatorial plane, one oxygen in the axial position (Figure 3), and a covalent linkage to the N<sup>ε2</sup> of His486. The negative charge of the oxygen atoms in the equatorial plane is compensated by hydrogen bonds donated by several hydrophilic and positively charged amino acids in the vicinity, including Lys341, Arg349, Ser416, and Arg480. The axial oxygen atom forms a hydrogen bond with the N<sup>δ1</sup> of distal His418, which is the proposed conserved catalytic residue in vanadium peroxidases.<sup>10</sup>

Both hydrophilic and hydrophobic residues cover the entrance channel with hydrophobic residues dominating the lower part near the vanadate-binding site. Interestingly, amino acid residues from both monomers contribute to the substrate

**Figure 3** The active site residues around the vanadate center of vanadium bromoperoxidase from *A. nodosum*. There are also three water molecules (W772, W773 and W761) in the active site. (Reprinted from Ref. 24, © 1999, with permission from Elsevier)

access channel of each active center. The channel to the active site of each monomer is 15 Å deep with a diameter of 12 Å at the entrance, decreasing to 8 Å near the axial oxygen of the vanadate prosthetic group, where the channel exhibits a more hydrophobic character.<sup>27</sup>

The X-ray structures of vanadium bromoperoxidases from the red seaweeds *Corallina pilulifera* and *C. officinalis* have also been determined and their structures are almost identical.<sup>28,29</sup> The native structure of these enzymes is dodecameric and the structure is made up of 6 homo-dimers. The secondary structure of the chloroperoxidase from the fungus *Curvularia inaequalis* that will be discussed later can be superimposed with the *Corallina* bromoperoxidase dimer. Many of the  $\alpha$  helices of each chloroperoxidase domain are structurally equivalent to the  $\alpha$  helices in the *Corallina* bromoperoxidase dimer. This is in line with the evolutionary relationship between the haloperoxidases that will be discussed later. The disulfide bridges in the enzyme from *A. nodosum* are not found in the enzyme from *Corallina* and the two remaining cysteine residues are not involved in disulfide bonds. Additionally, in this enzyme binding sites are present for divalent cations that seem to be necessary to maintain the structure of the active site cleft. All the residues directly involved in the binding of vanadate are conserved in the algal bromoperoxidases.<sup>30</sup>

An extraordinary feature of these enzymes is their remarkable stability.<sup>18</sup> The bromoperoxidase from the brown seaweed *A. nodosum* remains completely functional upon storage in up to 60% methanol, ethanol, and isopropanol for up to a month, and remains fully active when exposed

to temperatures up to 70 °C. The enzyme was observed to be unaffected by detergents and reagents such as guanidine-HCl and to withstand oxidative inactivation in the presence of high concentrations of highly reactive oxidants, including hydrogen peroxide and hypohalous acid.<sup>10</sup> The high stability of this enzyme can be attributed to the highly rigid core of the dimeric enzyme and to the fact that more than 46% of the surface of each monomer is part of the dimer interface. In addition, 2 intermolecular salt bridges contribute to the stability of the homo-dimeric enzyme structure. The stability of the enzyme from *Corallina* appears to be the result of the dodecameric structure that shields the solvent accessible area. These fascinating features are of considerable interest for the potential application of the vanadium peroxidase as (industrial) biocatalyst in organic synthesis.

### 3 VANADIUM CHLOROPEROXIDASES

#### 3.1 Discovery and Physiological Function

During the course of screening for haloperoxidases with tolerance to high pH environments and high temperatures, it was observed that dematiaceous hyphomycetes isolated from plant material and soils collected in Death Valley possessed haloperoxidase activity.<sup>31</sup> In 1993, it was shown<sup>32</sup> that the nonheme chloroperoxidase produced by one such hyphomycete, the fungus *Curvularia inaequalis* also contains vanadate as the prosthetic group in the enzyme. These peroxidases escape detection if classical peroxidase assay systems (e.g. guaiacol) are used and consequently it took a long time to identify the peroxidases in hyphomycetes. Furthermore, when the fungus is grown in vanadate-deficient media, the enzyme is secreted in an inactive apoform.<sup>10</sup> Expression studies showed that the vanadium enzyme is produced in the secondary growth phase, when nutrients become limiting and the expression appears to be mainly regulated at transcription level.<sup>33</sup> Several species in the group of the dematiaceous hyphomycetes produce haloperoxidases (e.g. *Drechslera biseptata*, *D. subpapendorfii*, *Embellisia didymospora*, and *Ulocladium chartarum*), which are vanadium chloroperoxidases.<sup>10</sup> Thus, vanadium chloroperoxidases occur widely in nature. Many of these hyphomycetes are phytopathogenic and/or saprophytes and this raises the question of the physiological function of the vanadium chloroperoxidases. It has been proposed that the generated HOCl is used by the fungus as an attack mechanism to oxidize the lignocellulose in the cell walls of the plant in order to facilitate penetration of the fungal hyphae into the host.<sup>33</sup> It may well be that HOCl which is generated by fungi in soils also reacts with organic matter resulting in the formation of these organohalogens in plants and soil. This may explain the presence of chlorinated compounds in soils that are of nonanthropogenic origin.

### 3.2 Kinetic and Other Properties of Chloroperoxidases

Research on the vanadium chloroperoxidase obtained a large impetus by cloning of the gene encoding vanadium chloroperoxidase<sup>31</sup> and successful expression of the recombinant enzyme.<sup>33,34</sup> The gene encodes a protein of 609 amino acids with a calculated molecular mass of 67 488 Da. The apoform of the enzyme, either secreted by the fungus or produced as recombinant enzyme, can easily be activated upon addition of vanadate to the growth medium.<sup>10,32</sup> Thus, these enzymes do not require an additional enzyme system for the incorporation of vanadate. In most soils, a high concentration (100 ppm) of vanadium is present and considering the reported affinity of the apochloroperoxidase for vanadate ( $K_d$  140 nM), the amount of vanadium is not a limiting factor in the conversion of the apoenzyme into the holo-enzyme. Additionally, in the presence of  $H_2O_2$  the affinity of the apoenzyme for vanadate increases at least 200-fold. This appears to be due to the formation of pervanadate that binds much more strongly to the active site than vanadate.<sup>35</sup>

Steady-state kinetic studies<sup>36,37</sup> showed that the kinetics of the enzyme resemble those of the vanadium bromoperoxidases.<sup>16,19</sup> The chloroperoxidase exhibits a pH profile similar to vanadium bromoperoxidases although the optimal pH of 4.5–5.0 is at a lower value. At low pH the enzyme is inhibited by chloride in a competitive way whereas at higher pH values the activity displays normal Michaelis-Menten type of behavior (*see Michaelis Constant*). The log  $K_M$  for chloride increases linearly with pH whereas that for hydrogen peroxide decreases with pH demonstrating that in the catalytic mechanism protons are involved. These observations have led to a simplified ping-pong type of mechanism for the chloroperoxidase similar to that shown in (Figure 1).

The enzyme will first react with peroxide to form a peroxointermediate, after which a chloride ion and a proton react resulting in the formation of an enzyme-HOCl, which decays in a rate-determining step to enzyme and free HOCl.<sup>35</sup> The linear dependency of the log  $K_M$  for hydrogen peroxide on pH suggests that an ionizable group is involved in the binding of hydrogen peroxide. When this group is protonated hydrogen peroxide is unable to bind. The linear dependence of the log  $K_M$  for chloride on pH shows that for binding of chloride to occur, protonation of a group is essential.<sup>10</sup>

The binding of substrates to the chloroperoxidase has also been studied using substrate-induced spectral changes. Figure 4 illustrates the UV–VIS absorption spectra of the vanadium chloroperoxidase. A band is present at 315 nm ( $\Delta\epsilon = 2.8 \text{ mM}^{-1} \text{ cm}^{-1}$ ) in the native enzyme which is not found in the apoenzyme. The absorption of this band decreases upon addition of hydrogen peroxide.<sup>35</sup> When chloride is added, the original intensity of the band is reformed as a result of halide oxidation. Stopped-flow studies were also carried out confirming the catalytic sequence of events and

**Figure 4** UV-VIS absorption spectra of 100  $\mu\text{M}$  chloroperoxidase at pH 8.3. Holo-enzyme was obtained by addition of 100  $\mu\text{M}$  vanadate to the apoenzyme and the peroxo form by addition of 100  $\mu\text{M}$   $H_2O_2$  to the holo-enzyme. (Reprinted with permission from Ref. 35. © 2000 American Chemical Society)

evaluation of the first-order rate constant for the binding of hydrogen peroxide to the enzyme ( $0.8 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$  at pH 5). Sequential mix studies show the first direct monitoring of the decay of the peroxo intermediate to the native enzyme during chloride oxidation, which consists of at least two steps.

The chloroperoxidase also has bromoperoxidase activity.<sup>34,37</sup> Compared to the vanadium bromoperoxidases the chloroperoxidase has a very high affinity for bromide ( $K_M$  about 5  $\mu\text{M}$ ). The enzyme is strongly inhibited by excess bromide and hardly any activity is observed at 100 mM bromide. An interesting difference is also observed between the bromo- and chloroperoxidase activity of this enzyme. As discussed before, the  $K_M$  for chloride is strongly pH dependent, whereas the  $K_M$  for bromide is hardly affected by pH as is also observed for the bromoperoxidase from *Ascophyllum nodosum*. An X-ray study proved that during turnover a peroxo intermediate is formed.<sup>38</sup> The peroxide is bound side-on and it has been proposed<sup>37,39</sup> that protonation of one of the oxygen atoms of the peroxide is required to allow the more difficult oxidation of the chloride. Protonation of the bound peroxide is not required for bromide oxidation since bromide is more easily oxidized. Based upon the effects of mutations of the active site residues, the following mechanism has been proposed.<sup>34</sup> By the Lewis acid properties of vanadium and the two positively charged arginine residues (Arg490 and Arg360), electron density is withdrawn from the bound peroxide. The bound peroxide is further polarized and activated by a conserved lysine residue (Lys353) that forms a hydrogen bond to one of the oxygen atoms. The kinetic studies suggest that protonation of the bound peroxide occurs thereby increasing its reactivity. The model to explain the difference in reactivity between a bromo- and a chloroperoxidase is shown in Figure 5.

**Figure 5** A possible explanation for the difference in reactivity between vanadium chloroperoxidase and bromoperoxidase<sup>39</sup>

After formation of the peroxide intermediate, the next step in catalysis is the nucleophilic attack by the halide breaking the oxygen–oxygen bond, resulting in formation of HOX or XO<sup>−</sup>.

All mutations of the active site residues result in enzymes that are dead or kinetically crippled. Most or all of the chloroperoxidase activity is lost; however, some mutants retain bromoperoxidase activity.<sup>10</sup> A similar effect has been observed in the bromoperoxidase from *Fucus distichus*. Mutation of a phenylalanine in the active site of the bromoperoxidase to an alanine yielded a mutant that only showed iodoperoxidase activity.<sup>40</sup> Satisfactory explanations have not been offered for these observations and neither the question regarding the factors important in tuning the reactivity of the haloperoxidases has been answered. Mutagenesis studies on both bromoperoxidase and chloroperoxidase of the only residue that differs in the two enzymes (Phe in chloroperoxidase versus His in bromoperoxidase) have not clarified this either.<sup>37,41</sup> It can only be concluded that the difference in oxidative ability between VBPO and VCPO as modeled in Figure 5 is not simply due to a single residue. This protonation of the bound peroxide may only occur when a specific hydrogen-bonding network is present that involves bound water molecules and that plays an important role in tuning the reactivity of these enzymes and thus many factors are involved.

### 3.3 Sulfoxidation Reactions

The haloperoxidases in the absence of halides but in the presence of hydrogen peroxide are also capable of catalyzing the sulfoxidation of organic sulfides with a very high enantioselectivity.<sup>41,42</sup> The bromoperoxidase from the brown seaweed *A. nodosum* produces the R-enantiomer of methyl phenyl sulfoxide (96% e.e.) under slightly acidic conditions, while the bromoperoxidase from the red seaweed *C. pilulifera* produces the S-enantiomer of this sulfoxide (55% e.e.). The bromoperoxidase from the seaweed *C. officinalis* was also observed to convert organic sulfides that structurally resemble indenenes to the S-enantiomer of the corresponding sulfoxides showing high selectivities. Also,

small sulfides, possessing a *cis*-positioned carboxyl group with respect to the sulfur atom, are rapidly converted to the corresponding sulfoxides with selectivities exceeding 95% e.e. The vanadium bromoperoxidase from *A. nodosum* catalyzes the sulfoxidation of racemic nonaromatic cyclic thioethers with kinetic resolution.<sup>43</sup> By using <sup>18</sup>O-labeled hydrogen peroxide, it was shown that the vanadium bromoperoxidase mediates the direct transfer of the peroxide oxygen to the sulfide in a selective manner, strongly suggesting that the aromatic sulfide binds near or at the active site with a relatively low affinity.<sup>43</sup> The *k*<sub>cat</sub> for the sulfoxidation reactions is low (1 min<sup>−1</sup>) compared to the brominating activity of the bromoperoxidase from *A. nodosum* (166 sec<sup>−1</sup>). Vanadium chloroperoxidase in contrast to vanadium bromoperoxidase appears not to be capable of mediating the direct and selective transfer of peroxide oxygen to methyl phenyl sulfide. This may be due to the high reactivity of the chloroperoxidase resulting in electron abstraction from the substrate and formation of a positively charged sulfur radical. This radical migrates from the enzyme and is subsequently converted to the sulfoxide via reaction with water.

### 3.4 Stability of Chloroperoxidase

The vanadium chloroperoxidases are highly resistant towards elevated temperatures; the midpoint temperatures determined from thermal denaturation curves range from 82 to 90 °C. It is also possible to store the enzyme at elevated temperatures and it has even been reported that incubation at 75 °C for 8 hours resulted in only a 20% loss of activity.<sup>40</sup> The factors contributing to the thermostability are the compactness of the molecule and the large amounts of  $\alpha$  helical structure found in the chloroperoxidase.<sup>30</sup> Pronounced chemostability and resistance towards oxidative agents such as H<sub>2</sub>O<sub>2</sub>, HOCl, and singlet oxygen have been reported.<sup>17,36</sup> Heme-containing peroxidases with their electron-rich aromatic ring system are much more easily oxidized and inactivated by oxidative agents (see *Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases*). In this respect, the vanadium haloperoxidases are unique and the ability of the

**Figure 6** Ribbon type representation of the vanadium chloroperoxidase from *C. inaequalis*. (Reproduced from A. Messerschmidt and R. Wever, *Proc. Natl. Acad. Sci USA*, 1999, **93**, 392. © 1996 National Academy of Sciences, U.S.A.)

enzymes to handle the oxidative substrate and product are the consequences of the nature of the active site.

### 3.5 X-ray Structure of the Vanadium Chloroperoxidase and Details of the Active Site

Both the 2.1 Å crystal structure of the native chloroperoxidase and recombinant chloroperoxidase at 1.66 Å resolution have been reported.<sup>30,44</sup> The enzyme molecule has an overall cylindrical shape (Figure 6) with a length of about 80 Å and a diameter of 55 Å. The protein fold is mainly  $\alpha$  helical with two four-helix bundles as the main structural motifs. The structure also contains some antiparallel  $\beta$  sheets. The very compact packing of the helical structure is different from other known protein structures. There are no disulfide bridges which is in contrast to the vanadium bromoperoxidase from *A. nodosum*.<sup>28</sup> The vanadium-binding center is located on top of the second four-helix bundle and the residues binding the prosthetic group span a length of approximately 150 residues in the primary structure.

The X-ray structure analysis of the active site (Figure 7a) shows that vanadium is bound as orthovanadate<sup>V</sup> in the same way as in the bromoperoxidases in which three oxygen atoms form a plane (bond length about 1.65 Å), the fourth oxygen is found at the apex (bond length 1.93 Å) which is in the range

of a vanadium<sup>V</sup> hydroxyl bond. It is hydrogen bonded to the nitrogen N<sup>δ1</sup> of His404.

The N<sup>ε2</sup> atom from a histidine (His496) ligating directly to the metal completes the trigonal bipyramidal coordination. The negative charge of the vanadate group is compensated by hydrogen bonds to three positively charged residues (Arg360, Arg490, Lys353). Further, the vanadate forms hydrogen bonds with a glycine (Gly403) and a serine residue (Ser402). There is also a histidine residue (His404) close to the apical hydroxyl moiety of the vanadate which may act as an acid/base group in catalysis. These residues are in fact the same as in bromoperoxidase and the active sites are structurally nearly superimposable.<sup>10</sup> The pocket where vanadate is bound is at the end of a channel which supplies access and release of the small substrates and products of the reaction. Part of the surface of the channel is mainly hydrophobic with Pro47, Pro221, Trp350, Phe393, Pro395 as contributing side chains. The other half of the channels is predominantly polar with several carbonyl oxygens and the ion pair Arg490-Asp292. It is interesting to note that the Arg490 is also directly bound to the orthovanadate. A prominent difference in the active site architecture of the bromo- and chloroperoxidase is the presence of a second histidine in the bromoperoxidase, a residue substituted by a phenylalanine in chloroperoxidase.<sup>24</sup> Site-directed mutagenesis of this residue into a histidine partially abolished the chlorinating activity and surprisingly the mutant showed a higher  $k_{\text{cat}}$  in the bromination reaction at high pH values than the native enzyme.<sup>37</sup>

### 3.6 Homology Between Haloperoxidases and Acid Phosphatases

The vanadate-binding residues in the active site of the vanadium chloroperoxidase were shown to be conserved in two bromoperoxidases from seaweeds and a large group of phosphatases including glucose-6-phosphatase.<sup>45</sup> Based on the sequence similarity, it was concluded that the architecture of the active sites in the two classes of enzymes is very similar.<sup>45</sup> The X-ray structure of the acid phosphatase from *Escherichia blattae* (Figure 7b) confirmed the remarkable similarity of the residues binding the oxyanions.<sup>46</sup> Sulfate cocrystallizes with the acid phosphatase and its binding site is comparable to that of vanadate in the chloroperoxidase. Remarkably, the apochloroperoxidase has some phosphatase activity though the turnover with *para*-nitrophenyl phosphate as a substrate is about 10 000 times slower than that of the various acid phosphatases. However, the  $K_M$  for the substrate is of the same order of magnitude as various acid phosphatases. The data show that the active site of the haloperoxidase has a good affinity for the substrate but is not optimized for phosphatase activity.

Similarly, when vanadate is introduced in the active site of the acid phosphatases, these artificial enzymes are able to oxidize bromide in the presence of H<sub>2</sub>O<sub>2</sub> and to sulfoxidize sulfides in an enantioselective manner. The turnover frequency

**Figure 7** The active site of vanadium chloroperoxidase from *C. inaequalis* (a) and the acid phosphatase from *E. blattea* (b)

of the bromide oxidation and the specificity constant are however very low. The family of acid phosphatases that contains this active site is very large. These include glucose-6-phosphatase, lipid phosphatases from bacteria and yeast, and lipid phosphatases from higher eukaryotes that are involved in signal transduction and secreted bacterial acid phosphatases. Proteins from this superfamily have different physiological functions and are found in species varying from *E.coli* to humans. However, vanadium-containing haloperoxidases have thus far only been isolated from eukaryotes and are not detected yet in prokaryotes. Since phosphate and phosphate-metabolizing enzymes have entered evolution in an early stage it seems likely that vanadate was coined by nature to become the prosthetic group in the vanadium-containing haloperoxidases at a more recent stage and thus that these enzymes have evolved from the phosphatases.

## 4 VANADIUM IN TUNICATE VANADOCYTES

### 4.1 Introduction

Ascidians or tunicates (Phylum Chordata) belong to the class of Ascidiacea and are common marine animals whose body is enclosed in a jacket or tunic. The animals are attached to rocks and are either solitary or colonial. They continuously filter seawater to obtain minute organisms and particulate organics. As was originally discovered by Henze<sup>47</sup> the animals concentrate vanadium from seawater to levels about  $10^6$  times that present in seawater (35 nM), a phenomenon that has attracted considerable interest. The transition metal is present

in very high concentrations (up to 150 mM) in certain blood cells of the animal.

### 4.2 Cell Types

There is considerable confusion concerning the cells that contain vanadium. Tunicates possess several types of blood cells: lymphocytes, leucocytes, pigment cells, and cells containing vacuoles, that is, signet ring cells, morula cells, and compartment cells. The bulk of the vanadium is contained within the signet ring cells and compartment cells. Morula cells were originally thought to be involved in the accumulation of vanadium and thus were named vanadocytes. However, from a comparison of vanadium distribution over the 4 bands of blood cells from *Ascidia gemmata* and *A. ahodori* with the main population of the various cells in these bands, it was concluded that the morula cell contains little or no vanadium.<sup>11</sup> This was confirmed recently by scanning X-ray microscopy at the European Synchrotron Radiation Facility.<sup>11</sup> The data also clearly show that vanadium is present in the vacuoles in the signet ring cells of *P. mammallita* blood cells. In contrast, in *A. ceratodes* and *A. mentula* a significant amount of vanadium is also found in the morula cells. Clearly the presence of vanadium in a cell type depends on the species investigated and there is not a specific vanadocyte in the various *Ascidia*. Thus care should be taken not to extrapolate results from one species to another even if they are closely related.

### 4.3 Valence State and Intracellular pH

A number of biophysical techniques have been used to probe the valence state of vanadium in blood cells and their intracellular pH. Most data suggest a predominance

of vanadium<sup>III</sup>; the vanadium<sup>IV</sup> state which can be detected by EPR, is probably due to oxidation by oxygen.<sup>48</sup> Similarly, Magnetic Susceptibility Measurements show that vanadium<sup>III</sup> is the predominant species in the blood sample of *A. nigra*.

pH measurements showed that for signet ring cells of *A. gemmata*, *A. ahodori*, and *A. sydneinsis*, which contain the highest concentration of vanadium, pH values of 2.4, 2.7, and 4.2, respectively, were found. These low pH values support the X-ray absorption spectroscopy (XAS) measurements,<sup>11,49</sup> which indicate that nearly all the vanadium is present in the form of unchelated vanadium<sup>III</sup> coordinated only to water. Whole blood cells also contain large amounts of intracellular sulfate as is evident from sulfur X-ray Absorption Near Edge Structure (XANES), suggesting that the vanadium<sup>III</sup> is present as a sulfato complex ion.<sup>11</sup> An aliphatic sulfonic acid analogous to cysteic acid was also identified, the overall concentration of which is unprecedented in marine organisms and is comparable to that of sulfate in the blood cells and further, is approximately equal to that of vanadium. There are no clues as to the role of the high levels of the sulfate in vanadocytes.

The acidity of the blood cells is due to the low pH within the vacuole and a clear correlation between the acidity of the vacuoles and the concentration of vanadium in the vacuole has been shown.<sup>11</sup> An ATPase appears to be involved in generation and maintenance of the low pH. Addition of an ATPase inhibitor neutralizes the vacuole content. If one accepts that there is a link between the low pH in the blood cells and accumulation of vanadium, there is no need to invoke a mechanism stabilizing the vanadium<sup>III</sup> state since oxidation at low pH will not occur. Obviously there should be a mechanism to accumulate vanadium and to reduce the vanadate from seawater to the vanadium<sup>III</sup> state. A vanadium-binding protein vanabin has been identified that has a very high content of cysteine residues, its role may be trapping vanadium<sup>V</sup> and subsequent reduction to the IV state.<sup>50</sup> These vanadium-binding proteins bind up to 20 vanadium<sup>IV</sup> ions per mol of vanabin; however, the affinity for vanadium<sup>IV</sup> is not very high ( $K_d$  21  $\mu$ M) in view of the concentration of vanadium in seawater. The affinity of the vanabins for vanadium<sup>V</sup> has not yet been reported and may be much higher. The suggestion has been made that NADPH generated by the pentose phosphate pathway is involved in the reduction step. However, vanadium<sup>V</sup> is easily reduced to the IV state by most biological reductants. The reductant involved to reduce the IV state to the III state, however, remains a mystery.

Tunicates not only contain a considerable amount of vanadium but also contain the biomolecule tunicchrome which is mainly present in morula cells. Tunicchrome makes up 50% of the dry weight of these cells. This blood pigment consists of a class of tripeptides containing di- and trihydroxybenzene substituents with strong chelating and reducing properties towards transition metals such as iron and vanadium.<sup>11</sup> These compounds coordinate and reduce vanadium<sup>V</sup> and also vanadium<sup>IV</sup> to the III oxidation state. However, the signet ring

cells from the tunicates (*A. ahodori*) do not seem to contain tunicchrome and its role in the reduction of vanadate remains doubtful.<sup>11</sup>

The physiological role of the vanadium accumulation is still a mystery. Several proposals have been made in the last 5 decades. One proposal suggests that vanadium acts as an electron sink.<sup>51</sup> This sink for electrons may be used by the animals to regenerate NADP<sup>+</sup> when they are exposed to anaerobic conditions. It should be noted that there is apparently no oxygen transport system in the circulation of these animals and oxygen may often be limiting. Under aerobic conditions, the vanadium<sup>III</sup> may reoxidize to a higher oxidation state. It is clear that still many pieces of the puzzle relating vanadium uptake, redox reactions and low pH in the vacuoles are missing. However, the approach<sup>11</sup> to elucidate the functions of genes and proteins obtained from ascidian blood cells may well lead to clarification of the entire mechanism involved in accumulation and reduction of vanadium in ascidian vanadocytes.

#### 4.4 Vanadium in Fan Worms

Fan worms belonging to the genus *Pseudopotamilla* also contain a high concentration of vanadium.<sup>52</sup> Most of the vanadium in this worm is located in the branchial crown and more specifically in the vacuoles of the epidermal cells. Sulfur seems to be colocalized with vanadium. EXAFS spectral data on living *P. ocellata* indicate that most of the vanadium *in vivo* exists in the vanadium<sup>III</sup> state. Analysis of the XANES data indicates that the vanadium is present in solution in the form of an aqua complex with symmetrical octahedral coordination. Vanabin may also be present since the animal possesses antigens recognized by a monoclonal antibody raised against vanabin from *Ascidia sydneinsis*. The physiological role of vanadium in the animal is not known.

#### 4.5 Vanadium as a Terminal Electron Acceptor in Bacteria

Microbial reduction of metals of variable valence is a universal method by which microorganisms are able to regenerate NADH and this process is in general coupled to ATP synthesis. Vanadium has all the properties necessary for utilization by microorganisms in respiratory processes. The metal occurs in different oxidation states and it occurs extensively in the earth's crust. A search for bacteria in habitats rich in vanadium, like wastewater from a plant processing vanadium-containing slags, resulted in the finding that *Pseudomonas* strains under anaerobic conditions reduce vanadate to the tetra and trivalent states with organic electron donor as well as with molecular hydrogen and carbon monoxide.<sup>53</sup> Clearly, under anaerobic conditions, vanadate may act as the terminal electron acceptor in these bacteria. These observations give some weight to the hypothesis that vanadate in tunicates is also used as an electron sink under anaerobic conditions.

**Figure 8** X-ray structure of amavadine. (Reproduced by permission of Wiley-VCH)

## 5 AMAVADIN

The first report that vanadium occurs in fungal species dates back to 1931 when it was reported<sup>54</sup> that the fly agaric *Amanita muscaria* contains a high concentration of this element. Also in other *Amanita* species, such as *A. regalis* and *A. velatipes*, high amounts (up to 400 ppm) were found. Most other mushroom species have much lower vanadate concentrations. Apparently, vanadium is present in the IV state. The first EPR spectrum reported of an extract of the cap of the mushroom showed clearly an EPR signal characteristic of vanadium<sup>IV</sup>. The pale blue vanadium-containing compound from *A. muscaria* which was isolated later was named amavadine.<sup>55</sup> Structural elucidation has been controversial and many model complexes analogous to amavadine were reported.<sup>9</sup> Crystallization of the amavadine and structure determination gave the final clue to the peculiar structure of amavadin (Figure 8).<sup>56</sup>

The vanadium<sup>IV</sup> is eightfold coordinated to nitrogen in an unusual geometry and a V=O group is lacking. Amavadine possesses five chiral centers: four chiral centers all have the S configuration and the fifth chiral center is generated by the manner in which the ligands to the vanadium wrap around the vanadium atom.<sup>56</sup> The electrochemistry of amavadine is such that the compound may have a role in electron transfer reactions involving the vanadium<sup>V/IV</sup> redox couple. Studies have shown that amavadine can catalyze thiol oxidation.<sup>57</sup> Amavadine also has some peroxidase-like activity. In the presence of hydrogen peroxide it is able to oxidize halides and catalyze the hydroxylation and oxygenation of alkyl and aromatic substrates.<sup>9</sup> Interestingly,

it was reported recently by the Portuguese group that amavadine could convert methane into acetic acid in the presence of peroxodisulfate and trifluoroacetic acid. Other vanadium complexes could replace amavadine.<sup>58</sup> Despite all these studies, the physiological function of amavadine in mushrooms is still elusive.

## 1 INTRODUCTION

This article is essentially an update of the article of the same name published in the first volume of this Encyclopedia.<sup>1</sup> The present article includes a survey of the literature from the years 1992 to 2002 inclusive, but a number of references from the prior literature are included for continuity and completion. For ease of cross-reference, the format of the first article has also been retained as far as possible, with additions and deletions to reflect the advances in the chemistry of vanadium that have occurred since the period surveyed by the first article.

## 2 THE ELEMENT

### 2.1 Occurrence, Uses, and Properties

#### 2.1.1 Occurrence and Properties

Although the existence of vanadium was first claimed in 1801 by del Rio, it was identified independently in 1831 by Sefstrom who named the element vanadium after the Scandinavian goddess Vanadis. In 1869, Roscoe succeeded in isolating pure metallic vanadium by the reduction of VCl<sub>2</sub> with H<sub>2</sub> under conditions that required rigorous exclusion of air and moisture.

Vanadium is widely distributed in nature, it forms up to 0.05% of the earth's crust and there are over 60 vanadium ores. Vanadium occurs widely in coal and certain petroleum, especially those from Venezuela (up to 1%), in the form of oxovanadium(IV) porphyrins.<sup>1,2</sup> The major world producers of vanadium in recent years have been the United States, South Africa, and Finland.

The major industrial use of vanadium is in alloy steels and cast iron, to which it lends ductility and shock resistance. Commercial production is mainly as the iron alloy ferrovanadium, a tough, high-speed steel containing around 4–5% V. In ferrovanadium manufacture, vanadium pentoxide is reduced in an airtight electric furnace by ferrosilicon.<sup>1,3</sup>

The pure metal is much more difficult to obtain because of its reactivity with C, N<sub>2</sub>, H<sub>2</sub>, and O<sub>2</sub>. There are four different routes to its production; reduction of chlorides, reduction of the oxide, thermal dissociation of the iodide, and an electrochemical process.<sup>1,4,5</sup>

Vanadium has atomic number 23, atomic mass 50.94, and a density of 6.0 g cm<sup>–3</sup>. Bulk samples are inert to air, moisture, alkalis, and other nonoxidizing acids other than HF at 25 °C. However, the metal is attacked by conc. H<sub>2</sub>SO<sub>4</sub>, HNO<sub>3</sub>, and aqua regia. At elevated temperatures, vanadium combines with most nonmetals including N<sub>2</sub>, C, Si, and B to give a variety of products such as VC, VS<sub>2</sub>, V<sub>3</sub>Si, VB, and VB<sub>2</sub>. Most of these compounds are nonstoichiometric and interstitial. In air, V<sub>2</sub>O<sub>5</sub> is formed along with lower oxides.<sup>1,6</sup>

Vanadium metal forms definite compounds with several other metals and forms a solid solution in all proportions with titanium. It shows catalytic activity in a wide number of applications.<sup>1,6</sup>

Vanadium is an essential element<sup>7,8</sup> and the biochemistry of vanadium is dealt with elsewhere (see *Vanadium in Biology*). Here it is worth pointing out that the importance of vanadium in several biological systems has led to an upsurge in the extent and breadth of the coordination chemistry of the element.

The toxicity of vanadium is well known. No matter by which route the metal is absorbed, it acts by depressing the respiratory center, constricting the peripheral arteries of the viscera, and causing hyperperistalsis and enteritis. It has also been shown to be one of the few metals that can modify amino acid secretion. The effects of the vanadate(V) ion on the

cardiovascular system have been studied. Numerous enzymes are inhibited by vanadium ions or their complexes.<sup>1</sup>

### 2.1.2 Analytical Chemistry<sup>1,9,10</sup>

Analytical methods for the quantitative determination of vanadium by volumetric, colorimetric, or gravimetric techniques are all available.

**Chemical Methods.** In general, vanadium is reduced to the +II oxidation state by zinc amalgam, the vanadium can then be determined volumetrically by oxidation with a standard oxidizing agent (e.g.  $\text{KMnO}_4$ ) to the +V state. The formation of the reddish-brown peroxo-complex is used as the basis of a colorimetric technique for the determination of vanadium. Gravimetric techniques are not as useful for the determination of vanadium as the volumetric and colorimetric techniques.

**Spectroscopic Techniques.** In absorption spectroscopy, Vanadium(V), a  $d^0$  system, shows no transitions in the visible region. The yellow color of some  $\text{V}^{\text{V}}$  complexes can be ascribed to the tail of an intense absorption in the ultraviolet. Absorption spectroscopy is more useful for  $\text{V}^{\text{IV}}$  systems ( $3d^1$ ), where electronic energies of transitions generally correlate well with ligand type and with electron spin resonance (ESR) parameters.

<sup>51</sup>Vanadium NMR is a useful diagnostic tool for the detailed investigation of  $\text{V}^{\text{V}}$  coordination environments. The large magnetic moment of the <sup>51</sup>V nucleus, its high natural abundance (99.76%), and favorable relaxation properties make it a useful probe for the investigation of vanadium in its isolated complexes and in biological systems. This area has been reviewed recently.<sup>11–13</sup>

ESR spectroscopy is often used to study the  $\text{VO}^{2+}$  ion and its complexes. The unpaired electron is strongly coupled to the <sup>51</sup>V nucleus to give ESR spectra consisting of eight-line manifolds in frozen solution. The hyperfine coupling constants and *g*-factors are sensitive to the ligand field of the vanadium atom.<sup>1,7</sup>

Superhyperfine interactions are rarely observed in the ESR spectrum of the  $\text{VO}^{2+}$  ion because the unpaired electron interacts only weakly with the ligand nuclei, so that often the size of the coupling is less than the ESR bandwidth. This problem has been surmounted through the use of ENDOR spectroscopy.<sup>1,7</sup> In ENDOR spectroscopy, molecules with their  $\text{V}=\text{O}$  axes either parallel or perpendicular to the direction of the static magnetic field are selectively irradiated. In this way, the anisotropic superhyperfine coupling constants of <sup>1</sup>H and <sup>14</sup>N and the <sup>14</sup>N quadrupolar coupling constants can be obtained.

EXAFS has recently become more extensively used in the study of vanadium in complexes and in biology to investigate the nature of the local environment around the vanadium atom.<sup>14,15</sup>

## 3 BINARY COMPOUNDS

### 3.1 Hydrides

Vanadium can absorb hydrogen reversibly up to the final composition  $\text{VH}_{0.94}$  when heated at 300 °C in a 48.4% hydrogen atmosphere at 1 atm pressure.<sup>1</sup> The product is a gray metallic material whose brittleness increases with increasing hydrogen content. The structure is of a single phase having a tetragonal unit cell and lattice parameters  $a = 3.02$ ,  $c = 3.36$ .<sup>2</sup> A recent review on vanadium hydrides is available.<sup>16</sup> Stoichiometric vanadium hydrides such as  $\text{VH}_4$  have been observed spectroscopically<sup>17</sup> in an  $\text{H}_2$  matrix at 2–4 °K and coordination compounds containing V–H bonds are described later in this article (see Sections 4.3.2 and 4.4.2).

### 3.2 Halides

The halides are extremely important compounds providing convenient starting materials for other species. Their preparations and properties have been comprehensively reviewed elsewhere<sup>1,4,18</sup> and references to individual synthetic methods can be found in these works. The halides are discussed here in order of decreasing oxidation state.

#### 3.2.1 Pentavalent State

**Vanadium Pentafluoride,  $\text{VF}_5$ .** Vanadium pentafluoride is the only pentahalide so far reported. It is best prepared by direct reaction between metallic vanadium and fluorine in a flow system at 300 °C under moisture free conditions. It is an extremely reactive white solid at room temperature and an extremely powerful oxidizing and fluorinating agent.

Crystalline  $\text{VF}_5$  is isomorphous with  $\text{MoOCl}_4$  and the pentafluorides of Cr, Tc, and Re. The structure consists of infinite chains of octahedrally coordinated vanadium atoms linked by shared fluorine atoms.<sup>19</sup> In the gas phase, electron diffraction has shown  $\text{VF}_5$  to exist as a monomeric molecule having  $D_{3h}$  symmetry.<sup>20</sup>

#### 3.2.2 Tetravalent State

$\text{VF}_4$ ,  $\text{VCl}_4$ , and  $\text{VBr}_4$  are all well documented, but  $\text{VI}_4$  has been detected only in equilibrium mixtures and to date has not been isolated.

**Vanadium Tetrafluoride.**  $\text{VF}_4$  is formed along with  $\text{VF}_5$  and  $\text{VF}_3$  in the fluorination of metallic vanadium and the difference in volatilities of the three fluorides allows their separation by fractional sublimation. It can also be prepared by treatment of  $\text{VCl}_4$  with anhydrous HF in an inert solvent such as  $\text{CCl}_3\text{F}$  at –78 °C. Pure  $\text{VF}_4$  is a bright green hygroscopic solid, which disproportionates at 100 °C to  $\text{VF}_5$  and  $\text{VF}_3$ . Its structure consists of octahedrally coordinated  $\text{VF}_6$  units linked

by shared F atoms into polymeric strings.<sup>1,21</sup>  $\text{VF}_4$  reacts with  $\text{BF}_3$  or  $\text{F}_2$  to give  $\text{VF}_5$ , but is a weaker fluorinating agent than the latter.

*Vanadium Tetrachloride.*  $\text{VCl}_4$  is produced in the reaction between dry chlorine and vanadium or by the action of chlorinating agents such as  $\text{COCl}_2$ ,  $\text{SOCl}_2$ ,  $\text{S}_2\text{Cl}_2$ , or  $\text{CCl}_4$  on  $\text{V}_2\text{O}_5$  or the metal itself.<sup>1</sup> It is a reddish-brown, viscous liquid, mp =  $-26^\circ\text{C}$ , bp =  $153^\circ\text{C}$ , which is hydrolyzed readily in moist air. It is soluble in nonpolar solvents such as  $\text{CCl}_4$  and reacts violently with electron donor solvents to form adducts.  $\text{VCl}_4$  is monomeric in the vapor phase having a regular tetrahedral structure.<sup>1</sup> Decomposition of the tetrachloride to  $\text{VCl}_3$  and  $\text{Cl}_2$  occurs slowly at room temperature, even under a positive pressure of chlorine.

*Vanadium Tetrabromide.*  $\text{VBr}_4$  has been isolated by quenching ( $-78^\circ\text{C}$ ) the vapor obtained from heating the solid tribromide to  $325^\circ\text{C}$ . Although it is stable only up to  $-45^\circ\text{C}$ , decomposing to  $\text{VBr}_3$  and  $\text{Br}_2$ , its absorption spectrum in the range 200–600 nm has been obtained.<sup>22</sup>

*Vanadium Tetraiodide.*  $\text{VI}_4$  is unstable and has not been isolated, but its absorption spectrum has been observed in the range 230–500 nm in the vapor, and thermodynamic data for its dissociation into  $\text{VI}_3$  and  $\text{I}_2$  have been determined<sup>23</sup> ( $\Delta H^\circ = 104.8 \text{ kcal m}^{-1}$ ,  $\Delta S^\circ = 98.4 \text{ kJ m}^{-1}$ ).

### 3.2.3 Trivalent State

*Vanadium Trifluoride.*  $\text{VF}_3$  is prepared by passing anhydrous HF in  $\text{N}_2$  over  $\text{VCl}_3$  or  $\text{VCl}_2$  at  $600^\circ\text{C}$  in a platinum crucible. The structure is rhombohedral, each vanadium atom having an almost regular octahedron of fluorine atoms with the octahedra joined by shared corners.<sup>1</sup> Pure anhydrous  $\text{VF}_3$  is yellowish-green in color. It is slightly soluble in water, giving acidic solutions, and is virtually insoluble in organic solvents. It sublimes without decomposition at  $800^\circ\text{C}$ .

*Vanadium Trichloride.*  $\text{VCl}_3$  can be prepared by decomposition of vanadium tetrachloride under reflux or by heating the trioxide,  $\text{V}_2\text{O}_3$ , with thionyl chloride.<sup>1</sup> Its structure is similar to that of  $\alpha\text{-TiCl}_3$  and is composed of hexagonally close-packed chloride ions, with vanadium atoms occupying 2/3 of the octahedral interstices in alternate layers. Within a layer, each  $\text{VCl}_6$  octahedron has three neighboring  $\text{VCl}_6$  octahedra with which it shares edges.<sup>1</sup>  $\text{VCl}_3$  disproportionates above  $600^\circ\text{C}$ , to  $\text{VCl}_4$  and  $\text{VCl}_2$  and therefore cannot be sublimed. It is also extremely sensitive to traces of oxygen, which results in the formation of oxochlorides.

*Vanadium Tribromide.*  $\text{VBr}_3$  is formed directly from the reactions of bromine with vanadium or its nitride or carbide

at elevated temperatures.<sup>1</sup> More recently, it has been prepared from the reaction between  $\text{V}_2\text{O}_5$  and  $\text{CBr}_4$  and by treatment of  $\text{VCl}_4$  with dry HBr.<sup>24</sup> It is purified by sublimation at  $350^\circ\text{C}$  in a bromine atmosphere, which reverses the dissociation to  $\text{VBr}_2$  and  $\text{Br}_2$ . Anhydrous  $\text{VBr}_3$  is a grayish-black crystalline powder with a structure analogous to that of  $\text{VCl}_3$ .<sup>1</sup>

*Vanadium Triiodide.*  $\text{VI}_3$  can be prepared by reaction of vanadium metal with iodine at elevated temperatures. It is a brownish-black, hygroscopic crystalline powder, soluble in most nonpolar solvents, that begins to dissociate into  $\text{VI}_2$  and  $\text{I}_2$  at  $270^\circ\text{C}$ .<sup>1</sup>

*Vanadium Iodo-Chlorides.* The reaction of  $\text{VCl}_4$  with dry HBr has been reported to give the mixed halides  $\text{VClI}_2$  and  $\text{VCl}_2\text{I}$ .<sup>24</sup>

### 3.2.4 Divalent State

The preparations, structures, and properties of  $\text{V}^{\text{II}}$  halides have been reviewed.<sup>1,25</sup>

$\text{VF}_2$  forms deep blue crystalline needles having the rutile type structure with two  $\text{VF}_2$  units per unit cell.  $\text{VCl}_2$  and  $\text{VBr}_2$  can be prepared from the appropriate trihalide by their reduction by dihydrogen or by their disproportionation at an elevated temperature.  $\text{VI}_2$  can also be prepared by direct reaction of the elements.

$\text{VBr}_2$  has a layered triangular lattice in the range  $1.5\text{--}35^\circ\text{K}$  and is a Heisenberg antiferromagnet.<sup>26</sup> Two forms of  $\text{VI}_2$  are produced, depending upon the reaction temperature. The red form has the  $\text{CdI}_2$  structure; the black form is closely related but with mixed hexagonal and cubic close-packing of iodide ions.<sup>1</sup>  $\text{VCl}_2$  sublimes without decomposition in an inert or HCl atmosphere above  $900^\circ\text{C}$ . Similarly,  $\text{VBr}_2$  and  $\text{VI}_2$  sublime without loss of halogen in the range  $800\text{--}900^\circ\text{C}$ . The dihalides are hygroscopic and dissolve in water to yield blue–purple solutions of  $[\text{V}(\text{H}_2\text{O})_6]^{2+}$ . Acidic solutions of the dihalides are strongly reducing.<sup>1</sup>

## 3.3 Oxohalides

The oxohalides form an important set of compounds, closely related to the halides. Their preparations and properties are well-documented<sup>1,4,27,28</sup> and therefore only a summary is given here.

### 3.3.1 Pentavalent Oxohalides

The following oxohalides are known for vanadium(V):  $[\text{VOX}_3]$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ ) and  $\text{VO}_2\text{X}$  ( $\text{X} = \text{F}, \text{Cl}$ ); preparative routes are available for all.<sup>1,4</sup>

$[\text{VOCl}_3]$  is a pale yellow liquid with physical properties similar to  $\text{VCl}_4$ .  $\text{VOBr}_3$  slowly decomposes at  $25^\circ\text{C}$  to  $\text{VOBr}_2$

and  $\text{Br}_2$ . Both compounds are extremely unstable toward moist air. The gas-phase structures of  $[\text{VOCl}_3]$  and  $[\text{VOBr}_3]$  consist of trigonally distorted tetrahedra as predicted for  $[\text{VOF}_3]$ .<sup>1,4</sup>

### 3.3.2 Tetravalent Oxohalides

All the oxohalides of vanadium(IV),  $[\text{VOX}_2]$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ ), are known. In general, the complexes are green and monomeric and their chemistry is dominated by the strong vanadium–oxygen bond of the  $\text{VO}^{2+}$  group. The hydrates  $[\text{VOF}_2] \cdot 4\text{H}_2\text{O}$  and  $[\text{VOF}_2] \cdot 2\text{H}_2\text{O}$  are known and several hydrates of  $[\text{VOCl}_2]$  have been reported, of which the best known is  $[\text{VOCl}_2] \cdot 2.5\text{H}_2\text{O}$ , but many of their stoichiometries are uncertain.

### 3.3.3 Trivalent Oxohalides

Crystalline  $\text{VOCl}$ , prepared by reaction between  $\text{V}_2\text{O}_5$  and  $\text{VCl}_3$ , has a layered structure. Each oxygen atom is surrounded by a tetrahedron of vanadium atoms. Each vanadium atom is surrounded by four oxygen and two chlorine atoms in a distorted octahedral arrangement.<sup>1</sup>

## 3.4 Oxides (See Oxides: Solid-state Chemistry)

These have been described in a number of general texts.<sup>1,28</sup> In addition, a number of phases of intermediate composition have been identified, and the lower oxides, in particular, have wide ranges of homogeneity. There is a vast chemistry of polyoxovanadates, which are of interest with regard to their structural and catalytic properties,<sup>29,30</sup> but discussion of their chemistry is outside the scope of this article.

### 3.4.1 Pentavalent State

$\text{V}_2\text{O}_5$  is well known and has a structure that essentially comprises distorted trigonal bipyramids of  $\text{VO}_5$  sharing edges to form zigzag double chains.<sup>1,31,32</sup>  $\text{V}_2\text{O}_5$  loses dioxygen reversibly on heating, and this may partly explain its function as a catalyst in a wide variety of both organic and inorganic reactions, an important example being the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$  in the contact process for the manufacture of sulfuric acid. It is reduced by a number of reagents, such as  $\text{H}_2$ ,  $\text{C}$ ,  $\text{CO}$ ,  $\text{SO}_2$ , alkali metals,  $\text{Al}$ , and  $\text{Ca}$ . The products include the lower oxides,  $\text{VO}_2$ ,  $\text{V}_2\text{O}_3$ , and  $\text{VO}$ , as well as many other distinct oxide phases. With chlorine it forms oxotrichloride and dioxygen, and with metal oxides it forms vanadates.<sup>1</sup>

$\text{V}_2\text{O}_5$  is slightly soluble in water, producing a pale yellow, acidic solution that readily becomes colloidal. In alkalis, it dissolves to form colorless solutions, the nature of the species present depending upon the pH. At high pH, the orthovanadate ion  $[\text{VO}_4]^{3-}$  is formed, and at intermediate

pH a series of hydrolysis–polymerization reactions occur, forming isopolyvanadates.<sup>1,32</sup>

### 3.4.2 Tetravalent State

$\text{VO}_2$  may be prepared by the mild reduction of  $\text{V}_2\text{O}_5$  with reducing agents such as  $\text{CO}$ ,  $\text{SO}_2$ , oxalic acid, or hydroxylamine hydrochloride.<sup>1,28,33</sup> At room temperature, it has a distorted rutile structure but above 341 K, an undistorted rutile structure is adopted. Both phases consist of edge-sharing  $\text{VO}_6$  octahedra with similar O frameworks.<sup>34</sup> On passing from the low-temperature to the high-temperature form, the  $\text{V}^{4+}$ – $\text{V}^{4+}$  distance changes<sup>34</sup> from 2.7695 Å to 3.0794 Å.  $\text{VO}_2$  is amphoteric, dissolving in nonoxidizing acids to give solutions containing the blue oxovanadium(IV) (vanadyl) ion  $[\text{VO}]^{2+}$ , and in alkalis to give the yellow–brown vanadate(IV) (hypovanadate) ion  $[\text{V}_4\text{O}_9]^{2-}$ .  $[\text{VO}_4]^{4-}$  is formed at high pH.<sup>1</sup>

### 3.4.3 Trivalent State

$\text{V}_2\text{O}_3$  may be prepared by reduction of  $\text{V}_2\text{O}_5$  by reducing agents such as  $\text{C}$ ,  $\text{CO}$ , or  $\text{H}_2$ . It crystallizes with the corundum structure.<sup>1,28</sup> It is believed to possess only a narrow range of homogeneity.  $\text{V}_2\text{O}_3$  is antiferromagnetic, having a transition temperature of approximately 160 K. It is readily oxidized in air to  $\text{VO}_2$ , and may be reduced to the metal by calcium hydride. It reacts with thionyl chloride to give  $\text{VCl}_3$ .  $\text{V}_2\text{O}_3$  is basic, dissolving in aqueous acids to give blue or green  $\text{V}^{\text{III}}$  solutions that are strongly reducing.<sup>1</sup>

### 3.4.4 Divalent State

$\text{VO}$  is formed as a gray metallic powder by the reduction of higher oxides with a variety of reducing agents such as vanadium or potassium. It has a defect  $\text{NaCl}$  structure with a wide range of homogeneity,  $\text{VO}_{1.20}$ – $\text{VO}_{0.75}$ . Above 950 °C, in a vacuum, it decomposes into vanadium metal and  $\text{V}_2\text{O}_3$ . It is an electrical conductor and is paramagnetic between 77 and 300 K.  $\text{VO}$  is basic and dissolves in mineral acids to give a violet solution of vanadium(II).<sup>1</sup>

### 3.4.5 Other Oxides

In addition to the phases already mentioned, many others in the composition range  $\text{V}_2\text{O}_5$ – $\text{VO}$  have been investigated.<sup>1,28,35</sup> Between  $\text{V}_2\text{O}_5$  and  $\text{VO}_2$ , there is a succession of phases of general formula  $\text{V}_n\text{O}_{2n+1}$ , of which  $\text{V}_3\text{O}_7$ ,  $\text{V}_4\text{O}_9$ , and  $\text{V}_6\text{O}_{13}$  have been characterized.  $\text{V}_6\text{O}_{13}$  is obtained as a blue–black crystalline powder, and is formed by loss of oxygen from one-third of the  $\text{V}_2\text{O}_5$  [010] planes on heating. Between  $\text{VO}_2$  and  $\text{V}_2\text{O}_3$ , there is a series of shear phases, Magneli phases, of general formula  $\text{V}_n\text{O}_{2n-1}$ , based on a rutile structure

with periodic defects. Examples are  $V_8O_{15}$ ,  $V_7O_{13}$ ,  $V_6O_{11}$ ,  $V_5O_9$ , and  $V_4O_7$ .  $V_3O_5$ , which is also known, and  $V_2O_3$  and VO also conform to this general equation, but their structures are not related by chemical shear to those of the Magneli phases. On further reduction of the system, the corundum structure of  $V_2O_3$  is retained down to compositions as low as  $VO_{1.35}$ , after which VO is formed. This is also nonstoichiometric, with a composition range of  $VO_{0.75}$  to  $VO_{1.20}$ .

### 3.5 Sulfides

A number of vanadium sulfide phases, ranging from  $VS_4$  to  $V_3S_4$ , have been reported, although few have been well characterized and some may not exist at all. The structures, where known, are often complicated and difficult to describe.<sup>1,28,36</sup>

#### 3.5.1 $VS_4$

$VS_4$  may be prepared by the reaction of  $V_2S_3$  with an excess of sulfur at 400 °C. It is a diamagnetic black powder, with a fibrous structure similar to  $SiS_2$ , but with  $S_2^{2-}$  ions replacing  $S^{2-}$  ions. It is a semiconductor.  $VS_4$  is thermally unstable above 500 °C and dissolves readily in alkalis but not in acids.<sup>1,28</sup>

#### 3.5.2 $V_2S_5$

This compound is obtained by thermal decomposition of ammonium thiovanadate,  $(NH_4)_3[VS_4]$ . It is readily decomposed to  $V_2S_3$  and free sulfur, and this may be the reason for doubts about its existence.<sup>1,28</sup>

#### 3.5.3 $VS_2$

Little is known about this sulfide, which is believed to have the  $CdI_2$  structure.<sup>1,28</sup>

#### 3.5.4 $V_2S_3$

$V_2S_3$  has a range of homogeneity extending from  $VS_{1.17}$  to  $VS_{1.53}$ . It is obtained as a black paramagnetic solid from the reaction of  $H_2S$  on  $V_2O_3$ ,  $VO_2$ , or  $V_2O_5$ , or by treating  $V_2O_5$  with carbon disulfide at 700 °C. On heating to 850–950 °C in a vacuum, it dissociates into VS and sulfur. It is oxidized by air and nitric acid, but is insoluble in dilute alkali.<sup>1,28</sup>

#### 3.5.5 VS

This sulfide has a range of homogeneity extending from  $VS_{1.00}$  to  $VS_{1.16}$ . It is obtained as an air-sensitive

brownish-black solid by dihydrogen reduction of  $V_2S_3$  at 1000 °C or by reaction between the metal and sulfur in a sealed silica tube at 1000 °C. VS has the NiAs structure and is metallic with essentially temperature-independent paramagnetism.<sup>1,28</sup>

#### 3.5.6 $V_3S_4$

A high-temperature and a low-temperature form are known. The low-temperature form is hexagonal, isotopic with  $Nb_3S_4$  and transforms above 825 °C to the monoclinic form, which is stable above 950 °C. This form is isostructural with  $Cr_3S_4$ .<sup>37,38</sup>

#### 3.5.7 $V_5S_4$

This sulfide is tetragonal and isostructural with  $Ti_5Te_4$ .<sup>1,28</sup>

### 3.6 Sulfates

The only simple sulfates of vanadium are formed in the oxidation states +3 and +2. Vanadium(III) sulfate can be crystallized as a hydrate from aqueous solution, and is strongly reducing. It gives rise to a series of alums of the type  $M^IV(SO_4)_2 \cdot 12H_2O$ , which have been shown to contain the  $[V(H_2O)_6]^{3+}$  ion. The ammonium alum,  $(NH_4)V(SO_4)_2 \cdot 12H_2O$ , is obtained as air-stable blue–violet crystals by electrolytic reduction of  $NH_4[VO_3]$  in sulfuric acid.<sup>1,28</sup>

The violet divalent sulfate  $VSO_4 \cdot 7H_2O$  may be prepared by electrolytic sodium amalgam, or by zinc reduction of a solution of vanadium pentoxide in sulfuric acid, followed by evaporation of the resulting solution in a vacuum over phosphorous pentoxide. It is also strongly reducing, and evolves dihydrogen in water, but not in acid solution. The hexahydrate,  $VSO_4 \cdot 6H_2O$ , is obtained by electrolytic reduction of vanadyl(IV) sulfate solution.<sup>21,28</sup>

Both the hepta- and hexahydrate give rise to the reddish-violet Tutton's salts,  $M_2[V(H_2O)_6] \cdot (SO_4)_2$  ( $M = NH_4, K, Rb$ , or  $Cs$ ), on treatment of an aqueous solution of the salt with the appropriate alkali metal sulfate. These salts have the schonite,  $K_2Mg(SO_4)_2 \cdot 6H_2O$ , structure. They are more stable than the simple sulfate, especially in the presence of excess acid.<sup>1,28</sup>

### 3.7 Selenides and Tellurides

Several studies have been carried out on the vanadium–selenium and vanadium–tellurium systems,<sup>1</sup> and some of the components of these systems are described below. Vanadium diselenide,  $V_{1+x}Se_2$  ( $0.02 < x < 0.18$ ) has a structure of the  $Cd(OH)_2$ –NiAs type. Several other phases, such as  $V_5Se_8$ ,  $V_3Se_4$ , and  $V_7Se_8$ , have ordered superstructures of this type. VSe has the hexagonal NiAs structure. The vanadium-rich

phase  $V_5Se_4$  has a tetragonal structure. The magnetic susceptibility of  $V_5Se_8$  increases significantly with temperature, but  $VSe_2$ ,  $V_3Se_4$ , and the selenides richer in vanadium are metallic, with essentially temperature-independent paramagnetism.<sup>1,39</sup>

Vanadium ditelluride,  $V_{1+x}Te_2$  ( $0.03 < x < 0.14$ ), has a monoclinic structure related to that of  $Cd(OH)_2$ . The nonstoichiometric phases  $V_5Te_8$  and  $Ve_3Te_4$  have superstructures intermediate between the  $Cd(OH)_2$  and  $NiAs$  types. The vanadium-rich phase,  $V_5Te_4$ , is monoclinic. The vanadium tellurides are metallic, with essentially temperature-independent paramagnetism.<sup>1,39</sup>

### 3.8 Nitrides

Vanadium nitride, VN, with a range of homogeneity from  $VN_{1.00}$  to  $VN_{0.71}$ , may be prepared as a grayish-violet powder by the action of dinitrogen on a mixture of  $V_2O_3$  and carbon at  $1250^\circ C$ , or by the reaction of vanadium and dinitrogen or ammonia at  $900$ – $1300^\circ C$ . It is also formed by the thermal decomposition of  $(NH_4)_3[VF_6]$  at  $600^\circ C$ . It has the sodium chloride structure. It reacts with alkalis to give ammonia, and it is also attacked by boiling nitric acid. Another phase,  $V_2N$ , with a range of homogeneity from  $VN_{0.5}$  to  $VN_{0.37}$  is also known.<sup>1</sup>

### 3.9 Phosphides, Carbides, Silicides, and Borides

The V/P, V/C, V/Si, and V/N systems have been studied over various composition ranges and the main phases correspond to the stoichiometries  $V_3P$ , VP, VC,  $V_3Si$ ,  $V_5Si_3$ ,  $VSi_2$ ,  $V_3B_2$ , VB,  $V_3B_4$ , and  $VB_2$ .<sup>1</sup>

### 3.10 Phosphates

The binary phosphate  $V(PO_3)_3$  can be prepared by heating  $V_2O_5/H_3PO_4/H_2SO_4$  mixtures at  $300^\circ C$ . The structure is monoclinic consisting of a mixed network of  $VO_6$  octahedra and  $PO_4$  tetrahedra bonded at the apices into chains.<sup>1,28</sup>

## 4 COORDINATION CHEMISTRY OF VANADIUM

### 4.1 Introduction

The coordination chemistry of vanadium is dominated by its variable oxidation numbers, which range over the  $-I$ ,  $0$ ,  $+I$ ,  $+II$ ,  $+III$ ,  $+IV$ , and  $+V$  states. A very large number of compounds have been prepared, particularly for the higher oxidation states, since the previous edition of this Encyclopedia and reviews have appeared on general coordination chemistry,<sup>40–43</sup> structural advances,<sup>44</sup> aqueous vanadate chemistry,<sup>45</sup> and biologically related topics,

including vanadium as a phosphate analogue, haloperoxidases, amavadin, and other biological systems,<sup>46–48</sup> and modeling of vanadium nitrogenase.<sup>46,49</sup>

Much of the recent coordination chemistry of vanadium has been stimulated by interest in the biological significance of the element. Vanadium is important in both reductive<sup>49</sup> and oxidative catalytic transformations<sup>46–48</sup> in biological chemistry (see *Vanadium in Biology*).

Vanadium is known to exist in petroleum and shale deposits as a porphyrin complex.<sup>50</sup> Many catalytic processes that take place in oil production or advanced coal conversion may be critically affected by the presence of trace amounts of vanadium. Also it is known that vanadium, in combination with S compounds, can cause problems in oil hydroprocessing. Investigation of the manner in which V is present in coal, oil, and bitumen has resulted in many studies on porphyrin complexes of  $V^{IV}$  and  $V^{II}$ .<sup>50,51</sup>

The types of coordination complexes known for vanadium in its various oxidation states are discussed in the following sections.

### 4.2 Coordination Complexes in Low Oxidation States (<2) (See also *Vanadium: Organometallic Chemistry*)

Complexes containing vanadium in low oxidation states, apart from organometallic compounds, are known with ligands such as bipy, phen, nitric oxide, and tertiary phosphines, which stabilize such oxidation states.<sup>1</sup> Depending on their electronic structure,  $V^I$  and  $V^{-I}$  complexes may be diamagnetic, which permits study by NMR spectroscopy, and EPR spectroscopy has been used to study paramagnetic  $V^0$  complexes.

#### 4.2.1 Vanadium(-I)

Reduction of  $[V(bipy)_3]I_2$  with the metals Mg or Zn yields the complex  $[V(bipy)_3]$ , which will undergo further reduction by lithium aluminum hydride to  $Li[V(bipy)_3] \cdot 4THF$ , which formally contains  $V^{-I}$ . Similarly, reduction of  $[V(phen)_3]$  with dilithium naphthalene or dilithium benzophenone in THF yields  $[V(phen)_3]I_2$ . Further reduction with dilithium benzophenone gives the  $V^{-I}$  complex  $Li[V(phen)_3] \cdot 3.5THF$ . The terpyridyl complex  $[V(terpy)_2]$  can be obtained as black crystals by reduction of DMF solutions of  $[V(terpy)_2]I_2$  with Mg or  $LiAlH_4$ . Such low oxidation state complexes are highly air sensitive and decompose if heated to  $100$ – $200^\circ C$  in a vacuum. In these systems, the ligands may have an anion radical character.<sup>1</sup>

Tertiary phosphines, together with dinitrogen ligands, stabilize the V(-I) state in complex anions such as *trans*- $[V(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2]^-$ , whose X-ray structure is known, and *cis*- $[V(N_2)_2\{(Ph_2P)(CH_2CH_2PPh_2)_3\}]^-$ .<sup>52</sup> Monodinitrogen compounds as well as complexes with monodentate

phosphines have also been obtained, however, most complexes are unstable in the solid state even under a dinitrogen atmosphere.<sup>52</sup>

Nitrosyl ligands also stabilize  $V^{-I}$  complexes because, like dinitrogen, they are good  $\pi$ -acceptors that serve to remove electron density from electron-rich metals. Thus, addition of bpy or phen to an aqueous solution of  $[V(CN)_5(NO)]^{3-}$  gives the complexes  $[V(NO)_2L_2][CN]$  ( $L$  = bpy or phen), and similar products were obtained from mixtures of  $H_2VO_4^-$ , hydroxylamine hydrochloride and pseudo-halides, such as  $NCS^-$  or  $N_3^-$ .<sup>53</sup>

#### 4.2.2 Vanadium(0)

EPR spectroscopy has been used to study the  $[V(bpy)_3]$  complex and demonstrate that the single unpaired electron is extensively delocalized on the bipyridyl ligands.<sup>54</sup> The  $V^0$  complex  $[V(PF_3)_6]$  has been prepared by the oxidation of  $[Na(diglyme)_2][V(PF_3)_6]$  with benzenediazonium tetrafluoroborate.<sup>55</sup>

#### 4.2.3 Vanadium(I)

Some nitrosyl complex compounds have been prepared in which the vanadium center is formally  $V(I)$ . They carry the triethanolamine (tea) coligand and the vanadium in a structurally characterized example,  $[V(NO)(tea)]^-$ , is in a distorted, trigonal-bipyramidal environment with the amine and nitrosyl nitrogen donors in the axial positions.<sup>56</sup>

### 4.3 Vanadium(II) Coordination Complexes

The preparation of complexes of  $V^{II}$  was hampered in the past by their easy oxidation.<sup>1,43,57</sup> However, as techniques for the handling of air- and moisture-sensitive compounds have become more routine, the number of synthetic routes to such complexes and the types of complexes formed have increased.

Until recently, the majority of  $V^{II}$  coordination complexes contained the hydrated  $V^{2+}$  ion, obtained by reduction of acidic solutions of  $V^V$ ,  $V^{IV}$ , or  $V^{III}$ . The solutions are strongly reducing, and are oxidized by water with the evolution of dihydrogen. Several crystalline salts containing the  $[V(H_2O)_6]^{2+}$  ion are known. The most important of these is the sulfate,  $VSO_4 \cdot 6H_2O$ , formed by reduction of  $V_2O_5$  solutions in  $H_2SO_4$ , and the double sulfates (Tutton's salts),  $M_2[V(H_2O)_6](SO_4)_2$  ( $M$  =  $NH_4$ ,  $K$ ,  $Rb$ , or  $Cs$ ).<sup>1,43,57</sup> The solid-state structures of several vanadium(II) hydrates have been obtained by X-ray structural or neutron diffraction methods.<sup>58</sup>

Most  $V(II)$  complexes have predominantly N-, O-, S-, P-, and halide donor ligands. They are presented below in terms of the predominant ligand in the coordination sphere.

#### 4.3.1 Oxygen Ligands

Mononuclear octahedral complexes have been obtained for carbonyl-bound acetic acid,<sup>59</sup> and five-coordinate complexes of sterically hindered phenoxides of the type  $[V(py)_3(C_6H_3Ph_2-2,6)_2]$ .<sup>60</sup> A more hindered phenol gave a four-coordinate complex,  $[V(C_6H_3Pr_2-2,6)_4Li(thf)_2]$  in which two pairs of *cis*-phenolates were linked by a single  $Li(thf)^+$  unit.<sup>61</sup> A binuclear complex of a substituted acetylacetone<sup>62</sup> has the structure shown in (1).

#### 4.3.2 Nitrogen and Phosphorus Ligands

A general synthetic route to a range of  $V^{II}$  complexes has involved well-characterized precursor complexes in this oxidation state.<sup>1,43</sup> Thus, the anion  $[V_2(\mu-Cl_3)(thf)_6]^-$  has been used<sup>43</sup> to give complexes with diamino, pyridyl, and pyrrolidyl ligands and *trans*- $[VCl_2(Me_2NCH_2CH_2NMe_2)_2]$  has been used as a starting material for complexes of organic amidates  $[RNC(R^1)NR^-]$  and acetanilide  $[PhNC(Me)O^-]$  ligands.<sup>63</sup> Amidinate and amide ligands have been used to prepare dinitrogen complexes such as  $[V\{(SiMe_3)NC(Ph)N(SiMe_3)_2\}_2(\mu-N_2)]$ , which reacts reversibly with thf to give  $[V\{(SiMe_3)NC(Ph)N(SiMe_3)_2\}_2(thf)_2]$ .<sup>64</sup> Complexes of tertiary phosphine ligands include  $[VX_2(R_2PCH_2CH_2PR_2)_2]$  ( $X$  = halide or  $BH_4^-$ ,  $R$  = Me or Et)<sup>1,43</sup> and the hydride-bridged complex cation  $[V(PMe_3)_3]_2(\mu-H)^+$ .<sup>65</sup>

Vanadium(II) heterocyclic amine complexes of the type  $[VX_2L_4]$  and  $[VL_6]X_2$  ( $L$  = heterocyclic amine, e.g. pyrazole, imidazole, 2-methylimidazole, benzimidazole, isoquinoline;  $X$  = anionic ligand) have been known for some time and more recent examples of such complexes include polypyridyl  $V^{II}$  complexes of the type  $[V(terpy)(bipy)L]^n$ . Such complexes are obtained as a result of the disproportionation reaction of  $[V^{III}(terpy)Cl_3]$ , which yields  $[V^{II}(terpy)_2]^{2+}$  and  $[V^{IV}O]^{2+}$  in  $CH_2Cl_2$  suspensions.<sup>1</sup>

Low-valent metal porphyrins have been extensively studied, and show some promise in the understanding of the reactions of hemes with dioxygen. Until recently, there have been few examples of low-valent V porphyrins, presumably due to the stability of the oxovanadium(IV) species. The

first  $V^{II}$  porphyrins to be isolated have been obtained by reduction of nonoxo  $V^{IV}$  complexes of the type  $[V^{IV}X_2L]$  ( $X = Cl, Br$ ;  $L =$  porphyrinate(2-), OEP, TPP, TMTP, TPTP) by Zn amalgam to give  $[V^{II}Y_2L]$  ( $Y = thf, PPhMe_2$ ). The structures of both complexes  $[V^{II}Y_2L]$  showed that the two nonporphyrin ligands assume a trans configuration with the octahedrally coordinated V atom in the plane of the four porphyrin N atoms.<sup>1</sup> An octaethylporphyrinogen  $V^{II}$  complex was found to form a  $\mu$ -N dinuclear  $V^{III}$  complex.<sup>66</sup>

#### 4.3.3 Other Ligands

With halide ligands, complex cations of the type  $[L_3V(\mu-Cl)_3VL_3]$  ( $L = thf$  or 3-Me-thf) have been extensively studied and give a wide range of halide and other complexes by breaking up the dimer with ligands to give monomeric compounds, or by substitution into the dimer to give complexes such as  $[L_3V(\mu-Cl)_3VL_2(PPh_3)]$ .<sup>1,43</sup> Halide complexes of the type *trans*- $[VX_2L_4]$  ( $X = Cl, Br, I, SCN, N_3, PhS, EtS$  or  $BH_4$ ;  $L = py$ ) have been prepared.<sup>1,43</sup> Oligonuclear complexes have been prepared in addition to the dinuclear cations, these include the series of complexes having a very stable  $\{V_3Cl_3\}$  core, *triangulo*- $[V_3(\mu-Cl)_3(\mu_3-Cl)L_3]^+$  ( $L = MeOH, EtOH$ , etc.),<sup>43</sup> and a tetranuclear species  $[V_4(\mu_3-Cl)_2(\mu-Cl)_2(\mu-CF_3CO_2)_2(thf)_6]$ .<sup>67</sup>

Vanadium(II) complexes with sulfur-donor ligands are relatively rare. Those reported are prepared from the usual  $V^{II}$  precursors noted above. Thus *trans*- $[VCl_2(Me_2NCH_2CH_2NMe_2)_2]$  reacted with 1,2-bis(2-sulfido-phenylsulfanyl)ethane(2-) to give the mixed N,S ligated complex  $[V(2-SC_6H_4SCH_2CH_2SCH_2CH_2C_6H_4S-2)(Me_2NCH_2CH_2NMe_2)]$ . With the tridentate ligand, 1,4,7-trithiocyclononane,  $(9[ane]S_3)$ ,  $[V_2(\mu-Cl)_3(thf)_6]Cl$  gives  $[V(9[ane]S_3)_2(\mu-Cl)_3]Cl$  and  $[VI_2(thf)_4]$  gives the monomer  $[VI_2(thf)(9[ane]S_3)]$ .<sup>14</sup>

### 4.4 Vanadium(III) Coordination Complexes

Vanadium(III) complexes are most commonly prepared from  $V^{III}$  halides, principally  $VCl_3$ , or by electrolytic reduction of  $V^{IV}$  or  $V^V$  solutions. Most are readily oxidized or hydrolyzed in the presence of air or moisture.

Complexes with monodentate ligands are generally six-coordinate cationic or neutral species having octahedral stereochemistry with trigonal distortion. The electronic spectra and magnetic properties of many six-coordinate  $V^{III}$  complexes have been studied and are in accordance with those expected for a  $d^2$  ion in an octahedral field with trigonal distortion.<sup>1</sup>

More recent work has involved the preparation and characterization of vanadium(III) complexes with bidentate and multidentate ligands, especially those with nitrogen- and oxygen-donor atoms, because of their biological significance.

Hydride derivatives are of interest in connection with the catalytic properties of vanadium, for example, in alkene dehydrogenation or polymerization. Complexes with sulfur-donor and possibly also nitrogen-donor atoms are relevant to the role played by vanadium in the poisoning of the Co-Mo catalyst used for the hydrodesulfurization of crude oil.<sup>1</sup>

#### 4.4.1 Oxygen Ligands

The chemistry of the blue hexahydrate ion  $[V(H_2O)_6]^{3+}$  has been reviewed.<sup>1</sup> Complexes of alkoxides are of interest with regard to biological systems, particularly tunicates,<sup>46</sup> and to polymerization catalysis of alkenes.<sup>68</sup> Alkoxide and phenoxide complexes are often oligomeric and insoluble,<sup>1</sup> unless the O-donor carries bulky substituents, when soluble, mononuclear complexes can be isolated. Five-coordination is then common, for example, in  $[VCl(OC_6H_3Pr_2-2,6)_2(thf)_2]$ .<sup>69</sup> Binuclear complexes with phenoxides bridging six-coordinate vanadiums are also known, such as  $[V(OPh)_2(thf)]_2(\mu-OPh)_2]$ , and a binuclear complex with terminal esters,  $[VCl_2[CH_3C(O)OC_2H_5]_2(\mu-Cl)_2]$ , has also been prepared.<sup>70</sup>

With bidentate ligands, both mononuclear and complexes of higher nuclearities may be obtained. The acetylacetonate complex  $[V(acac)_3]$  has a monomeric, octahedral structure as do tris(oxalate) complexes and the oxalate anion  $[V(oxalate)_2(H_2O)_2]^-$ , but catecholate ligands form dinuclear complexes containing a linear oxide-bridged unit,  $[V(catecholate)_2(L)]_2(\mu-O)$ , which are interesting as polymerization procatalysts.<sup>1,68,71</sup> Carboxylate ligands also support oxo-bridged structures, which include complexes having the  $\{(\mu-oxo)-bis(\mu-carboxylate)\}$  core, in which the two  $V^{III}$  ( $d^2$ ) ions show antiferromagnetic coupling, and also the trinuclear oxo-bridged cations illustrated in (2).<sup>1,72</sup>

The tetranuclear compounds  $[V_4O_2(O_2CET)_7(bpy)_2][ClO_4]$  ( $bpy = 2,2$ -bipyridine), and the related complex  $[NEt_4][V_4O_2(O_2CET)_7(pic)_2]$  ( $pic = 2$ -picolinate) have a  $[V_4O_2]^{8+}$  'butterfly' core (3) and a  $S = 3$  ground state.<sup>73</sup>

Because of their biological relevance, complexes of bidentate amino acids and related ligands have been widely studied<sup>46</sup> (see *Vanadium in Biology*) and are merely mentioned here. Six-coordinated complexes of proline, phenylalanine, tryptophan, histidine, and valine have been prepared and structures are known.<sup>46,74</sup>

Some  $V^{III}$  complexes involving the ONO donor ligand pyridine-2,6-dicarboxylic acid, (DPA), include the seven-coordinated mononuclear complex,  $[V(DPA)(PA)(H_2O)_2]$

(PA = picolinate anion). This complex has a pentagonal bipyramidal structure with the equatorial plane accommodating the ONO and NO donor points, while the two water molecules occupy the axial positions.<sup>75</sup> Seven-coordination is more often seen with polydentate ligands, in particular, tetradentate EDTA and its analogues,<sup>1</sup> for example  $[\text{V}(\text{EDTA})(\text{H}_2\text{O})]$ , which is converted to a six-coordinated complex by protonation of an oxygen atom of the EDTA. Nitrilotriacetate (NTA) and related ligands are tridentate O-donors that give six-coordinated complexes of the type  $[\text{V}(\text{NTA})(\text{H}_2\text{O})_3]$ .<sup>76</sup>

#### 4.4.2 Nitrogen Ligands

A number of acetonitrile, pyridine, and related complexes are known. Examples are  $[\text{VX}_3(\text{RCN})_3]$  ( $\text{X}$  = halide;  $\text{R}$  = Me, Et, or Pr) and  $[\text{VCl}_3\text{L}_3]$  ( $\text{L}$  = pyridine and  $\gamma$ -picoline).<sup>1</sup>  $[\text{VCl}_3(\text{MeCN})_3]$  shows *fac*- and *mer*-isomers in solution and  $[\text{VCl}_3\text{py}_3]$  has the *mer*-structure in the solid state, with the pyridines twisted out of the metal–ligand planes.<sup>77</sup>

Polydentate N-donor ligands have been developed with the aim of stabilizing vanadium complexes with low-coordination numbers or with relatively rare ligands, such as hydride or dinitrogen, at vanadium in a higher oxidation state than those previously used (see Sections 4.2 and 4.3). Thus, tris(amide) ligands are used to obtain complexes with hydrides or dinitrogen as bridging ligands in  $[\{\text{V}[\text{Me}_3\text{SiN}(\text{CH}_2\text{CH}_2\text{NSiMe}_3)_2\}]_2(\mu\text{-H}_2)]$  and  $[\{\text{V}[\text{CH}_3\text{C}(\text{CH}_2\text{NPr})_3\}]_2(\mu\text{-N}_2)]$ ,<sup>78</sup> and the tridentate ligand  $\text{N}\{\text{CH}_2\text{CH}_2\text{N}(\text{C}_6\text{F}_5)\}_3$  gives the five-coordinated, monopyramidal complex shown in (4).<sup>79</sup>

There have been extensive studies of  $\text{V}^{\text{III}}$  complexes of polydentate N- and N,O-donor ligands. These include porphyrins and phthalocyanines.<sup>1,46</sup> X-ray structures have recently been obtained as exemplified in (5).<sup>80</sup>

Many complexes have been prepared using Schiff-base-type ligands,<sup>1,46</sup> which can be heptadentate and octadentate and give mononuclear or dinuclear complexes.<sup>1,46,81</sup>

#### 4.4.3 Sulfur Ligands

Compounds in this area have been studied with regard to biological systems and polymerization catalysis; multi-dentate ligands are generally used. L-cysteine gives<sup>46</sup> the anion  $[\text{V}(\text{L-cysteine})]^-$  and other mononuclear complexes are:  $[\text{VCl}_3(1,4,7\text{-trithiacyclononane})]$ ,<sup>14</sup> the trigonal bipyramidal hydrazine complex  $[\text{V}\{\text{N}(\text{CH}_2\text{CH}_2\text{S})_3\}(\text{N}_2\text{H}_4)]$ ,<sup>82</sup> and a series of complexes of the ligand  $[\text{O}(\text{CH}_2\text{CH}_2\text{S})_2]^{2-}$ , such as  $[\text{V}\{\text{O}(\text{CH}_2\text{CH}_2\text{S})_2\}(\text{OC}_6\text{H}_3\text{Pr}_2\text{-2,6})(\text{pyridine})]$ , which are catalyst precursors for olefin polymerization.<sup>83</sup>

Bidentate ligands can be used to generate both homo-metallic and hetero-metallic species. Thus, ethanethiolate (ent) gives<sup>84</sup> the anions  $[\{\text{V}(\text{ent})\}_2(\mu\text{-ent})_2]^-$  and  $[\{\text{VCl}_3\}_2(\mu\text{-ent})_3]^{3-}$  and 2-aminoethanethiolate gives a series of linear-type, S-bridged, trinuclear complexes<sup>85</sup> incorporating  $\text{V}^{\text{III}}$  together with  $\text{Rh}^{\text{III}}$  or  $\text{Ir}^{\text{III}}$ . Cubane-type cluster complexes of iron, sulfur, and vanadium, such as the anion  $[\text{VFe}_3\text{S}_4\text{X}_3(\text{dimethylformamide})_3]^-$  ( $\text{X}$  = halide), have been developed to mimic the behavior of the active center in vanadium nitrogenase and are discussed elsewhere (see *Vanadium in Biology*).<sup>46</sup>

#### 4.4.4 Halide and Other Ligands

Many examples of  $[\text{MX}_3\text{L}_3]$  complexes with N and P-donor ligands are known and recent X-ray structures generally confirm the proposed geometries for these octahedral compounds.<sup>1</sup> Halide bridges feature in polynuclear complexes of  $\text{V}^{\text{III}}$ , such as the structurally characterized anions  $[\{\text{VCl}_3\}_2(\mu\text{-Cl})_3]^{3-}$  and  $[\text{V}_3\text{OCl}_4\{\text{O}_2\text{C}(\text{C}_6\text{H}_4\text{SO}_2-2)\}_5]^-$ . The terminal and bridging halides of the former complex can be exchanged and the latter compound contains the triangular  $[\text{V}_3(\mu\text{-O})_3]^{7+}$  core structure seen in (2).<sup>72</sup> Linear oxo-bridged complexes of  $\text{V}^{\text{III}}$  with the  $\{\text{V-O-V}\}^{4+}$  core and such terminal ligands such as  $\text{PMe}_3$ ,  $\text{BH}_4^-$ , and 1,4,7-triazacylononane have been structurally characterized.<sup>1</sup>

### 4.5 Vanadium(IV) Coordination Complexes

#### 4.5.1 Introduction

This is the most stable and important oxidation state for vanadium. Aqueous solutions of  $\text{V}^{\text{III}}$  are air oxidized to  $\text{V}^{\text{IV}}$ , and  $\text{V}^{\text{V}}$  reacts with mild reducing agents to give  $\text{V}^{\text{IV}}$ . The blue oxovanadium(IV) cation  $[\text{VO}(\text{H}_2\text{O})_5]^{2+}$  is prevalent in aqueous solution and in many salts and is used as a starting material for a wide number of complexes. The vanadyl ion  $[\text{VO}]^{2+}$  dominates the aqueous chemistry of vanadium(IV) and this aspect of vanadium chemistry is effectively summarized in reviews that have already appeared.<sup>1,46,57</sup> The vanadyl ion is still ubiquitous in the more recent chemistry of vanadium(IV), but there has been a considerable expansion in the range of coordination compounds that do not contain the terminal oxo-group. We will discuss vanadyl complexes as a separate group, concentrating on examples from the recent past and outline the chemistry of nonvanadyl complexes according to the predominant donor atom in the coordination sphere of vanadium.

#### 4.5.2 Coordination Complexes of Vanadium(IV) Halides

The earlier coordination chemistry of vanadium(IV) was based upon complexes of  $\text{VX}_4$  formed generally by direct interaction with ligands in nonaqueous solvents. The majority of the complexes are of the type  $[\text{VX}_4\text{L}_2]$  ( $\text{X}$  = halide;  $\text{L}$  = O-, S-, Se-, N-, P or As-donor ligand), or are anionic complexes such as the hexachlorovanadate(IV),  $[\text{VCl}_6]^{2-}$ , with largely octahedral stereochemistries, showing some tetragonal distortion. The types of complexes formed, along with their methods of preparation, have been reviewed.<sup>1</sup> Simple oxohalide complexes  $[\text{VOX}_2\text{L}_2]$  and oxo-anions such as  $[\text{VOF}_4]^{2-}$  are also well known and are often used as precursors to the vanadyl complexes discussed in the following section.<sup>1,57</sup>

#### 4.5.3 Complexes of Oxovanadium(IV)

The  $\text{VO}^{2+}$  (vanadyl) ion is one of the most stable oxo-metal species known, and probably the most stable diatomic ion. Most of these properties stem from the ground-state electronic configuration of the vanadium atom,  $[\text{Ar}]3\text{d}^1$ , which shows similarities to the  $\text{Cu}^{2+} \text{d}^9$  system. The ion also lends itself to study by ESR because of the isotopic purity of the  $^{51}\text{V}$  isotope, its high nuclear spin,  $I = 7/2$ , and the single unpaired outer electron.

Examples of some of the main types of complexes formed by the  $\text{VO}^{2+}$  ion are shown in Table 1, which is a revised version of that found in Reference 1 in that it includes some recent examples, although most of the original entries are retained for continuity and because the structural pattern is largely unchanged. The complexes formed are classified according to the generalized formula.<sup>1</sup> Monodentate ligands are represented by lower case letters and multidentate ones by LL, LL', LL'/L'' and so on.<sup>1,46,86-90,90</sup>

The  $\text{VO}^{2+}$  ion bonds most effectively to electronegative donor atoms, that is, F, Cl, O, or N, but complexes having S-donor atoms are known. The vanadyl complexes formed are generally green or blue-green and can be neutral, anionic, or cationic. A commonly used starting reagent for the formation of  $\text{VO}^{2+}$  complexes is the sulfate,  $\text{VOSO}_4 \cdot 5\text{H}_2\text{O}$ , prepared by reduction of vanadium(V) in sulfuric acid. Probably, the most extensively studied complex of oxovanadium(IV) is  $[\text{VO}(\text{acac})_2]$ , which is also often used as a starting reagent for  $\text{VO}^{2+}$  compounds.<sup>1,46</sup> This stable complex has been used as a starting material for the preparation of mixed-ligand complexes by displacement reactions of one or both acac groups,<sup>1,86</sup> and has also been much used in physical studies of the nature of the  $\text{V}=\text{O}$  bond by spectroscopic and crystallographic techniques. The latter investigations indicate that the bond has a partial triple bond character with a predominant axial interaction and an equatorial component involving  $\sigma$ -bonding between the oxygen lone pairs and the  $\text{V } 3\text{d}_{xy}$  orbital.<sup>87</sup> This bonding system gives rise to a characteristic strong, sharp IR stretching frequency at around  $985 \pm 50 \text{ cm}^{-1}$ . The position of the  $\text{V}=\text{O}$  stretching frequency is insensitive to molecular changes in the coordination sphere of the V atom.

The vast majority of oxovanadium(IV) complexes have magnetic moments that lie within  $0.03 \mu_{\text{B}}$  of the spin-only value for one electron, that is,  $1.73 \mu_{\text{B}}$ . These are magnetically dilute complexes in which the metal ion is not involved in a magnetic exchange with the neighboring metal ions through exchange forces and the orbital contribution to the magnetic moment is quenched. Two complexes that show this behavior are  $[\text{VO}(\text{salicylaldimine})]$  and  $\text{VO}(\text{phthalocyanine})$ .<sup>1</sup>

The X-ray crystal structures of many oxovanadium(IV) complexes have been determined. In general, the  $\text{V}=\text{O}$  bond is shorter than most other  $\text{V}-\text{O}$  bond lengths, ranging between 1.57 and 1.68 Å, which is in keeping with the above view of the multiple characters of this bond.<sup>1</sup> The most common

<sup>a</sup>The general charge has been omitted from outside the square brackets.

stereochemistry for five-coordinate complexes of  $\text{VO}^{2+}$  is square pyramidal, as in  $[\text{VO}(\text{acac})_2]$ , although some trigonal bipyramidal structures are known. In complexes such as  $[\text{VO}(\text{acac})_2]$ , the O–V=O angle is greater than 90°; and the V atom lies above the plane formed by the four basal singly bonded oxygen atoms. Similar structural features occur in six-coordinate oxovanadium(IV) complexes, although the sixth ligand is often found to be only weakly coordinated and trans to the V=O bond in such structures.<sup>1</sup>

A great number of Schiff-base complexes of oxovanadium(IV) have been studied by X-ray diffraction. Many of these bases contain O,O,N,N-donor atoms in ligands formed from reaction between substituted salicylaldehyde and aliphatic or aromatic amines,<sup>1,46,88,89,91</sup> but examples with S-donor ligands have also been reported.<sup>92</sup> The distorted square

pyramidal geometry found for most of these complexes is analogous to that found with simpler ligands. In some cases, the structure of the Schiff-base complexes is polymeric with the sixth, vacant, position of the square pyramid being occupied by the oxygen atom of the vanadyl group of the adjacent molecule,<sup>1,46,91</sup> or a hydrogen-bonding interaction can occur, as shown in (6), where the formation of the binuclear complex makes this system more stable toward reduction to  $\text{V}^{\text{III}}$  than related complexes.<sup>88</sup>

Attempts to model the structure of the V-dependent bromoperoxidase enzyme have resulted in the characterization by X-ray crystallography of a great number of  $\text{VO}^{2+}$  complexes having N,N,N,N-donor atoms. The imidazole group is thought to mimic the protein environment and complexes such as  $[\text{VO}(\text{SALIMH})(\text{acac})(\text{MeOH})]$ ,  $[\text{VO}(\text{SALIMH})\text{SAL}]$ , and  $[\text{VO}(\text{SALIMH})_2(\text{EtOH})]$ , have been prepared<sup>1,46</sup> (see *Vanadium in Biology*).

The mixed valence  $[\text{V}^{\text{IV}}\text{O} - \text{V}^{\text{V}}]^{3+}$  bridge is a fairly common unit. It is found in complexes such as  $\text{Na}[\text{V}_2\text{O}_3(\text{DL-salser})_2] \cdot 5\text{H}_2\text{O}$ ,  $[\text{V}_2\text{O}_3(\text{S-peida})_2]^-$ ,  $[\text{V}_2\text{O}_3(\text{NTA})_2]^{3-}$ ,  $[\text{V}_2\text{O}_3(\text{pmida})_2]^-$ ,<sup>1</sup> and  $[\text{VO}\{\text{salen}(5\text{-Me})_2\}][\text{ClO}_4]$ .<sup>1,88</sup> Multinuclear complexes can also be obtained using Schiff-base ligands carrying pendant donor groups that can bind other metallic centers, such as in the  $\text{Gd}^{3+}$  adduct shown in (7), which shows a ferromagnetic interaction between the metals.<sup>90</sup> Similar complexes have also been obtained with catecholate ligands.<sup>93</sup>

Dinuclear complexes of vanadyl ions have been obtained where two such units are bridged by a tetradentate ligand, such as tartrate, citrate or *N,N*-bis(2-hydroxybenzyl)aminoacetate.<sup>95</sup> Dinuclear complexes with bridging alkoxide and carboxylate coligands are also known, structurally characterized examples include  $[\text{PPh}_4]_2[(\text{VO})_2\text{Cl}_4(\text{OR})_2]$  (R = CH<sub>3</sub> or CH<sub>2</sub>CH<sub>2</sub>Cl) and  $[(\text{VO})_2\text{Cl}_2\{\text{MeC}(\text{CH}_2\text{OH})(\text{CH}_2\text{O})_2\}_2]$ .<sup>96</sup>

Because of the interest in the nature of vanadium porphyrins occurring in petroleum and coal, there have been many studies on the syntheses of these complexes, their magnetic properties, and ESR spectra and structures.<sup>1,46,51</sup>

#### 4.5.4 Nonoxo Vanadium Complexes

A range of coordination complexes of  $V^{IV}$  has been prepared in which the vanadyl group is absent, a number of these compounds being synthesized as part of an effort to understand the nature of biological vanadium sites, such as amavadin,<sup>46</sup> which contains an octadentate, hydroxyiminodipropionate ligand bound to vanadium<sup>IV</sup>. A number of model complexes of this type have been prepared and discussion of this area can be found in the article *Vanadium in Biology*. Further discussion in this section follows the main ligand donor atom to vanadium.

**Nitrogen Ligands.** Amide ligands have been used to give four and five-coordinate complexes, such as  $[V(NMe_2)_4]^{97}$  and  $[V\{N(CH_2CH_2NR)_3\}X]$  ( $R$  = bulky substituent;  $X = Cl$  or  $N_3^-$ )<sup>98</sup> [see also (4)]. Treatment of  $[V(NMe_2)_4]$  with aniline gives the  $V^{IV}$  imido-complex  $[V(NMe_2)_2(NHMe_2)(=NAr)]$ , which with an excess of  $Me_3SiCl$  gives  $[V(NMe_2)_2Cl_2(=NAr)]$ .<sup>97</sup>

Vanadyl porphyrins, VOP, mentioned above [see (5)] have been used as precursors for nonoxo vanadium(IV) porphyrins,  $[VPX_2]$  ( $P = OEP, TPP, TMTP, TPTP$ ;  $X = Cl$  or  $Br$ ).<sup>1</sup> EXAFS at the Br K-edge has been used to confirm the trans configuration of  $X$  atoms in the complexes. The 'bare'  $V^{IV}$  atom renders the compounds extremely reactive and one theory is that they could act as precursors in the synthesis of complexes formed during coal conversion.<sup>1</sup>

N-donor macrocyclic ligands, based on 1,4,7-trithiacyclononane and carrying three pendant arms bearing alkoxides give nonoxo vanadium(IV) complexes.<sup>99</sup>

**Sulfur and Selenium Ligands.** Complexes containing the  $V=S^{2+}$  (thiovanadyl) moiety are known. The  $V=S$  bond

length, 2.061(1) Å, is longer than would be expected from comparison with analogous vanadyl complexes. This finding agrees with molecular orbital calculations, which predict a relatively weaker  $V=S$  bond.<sup>1</sup> Recently, the thiovanadyl, dithiocarbamate complexes  $[VS(S_2CNR_2)_2]^{100}$  and also the nonthiovanadyl derivatives  $[VX_2(S_2CNR_2)_2]$  ( $X$  = halide;  $R$  = alkyl) have been prepared.<sup>101</sup>

The tridentate, dithiolate ligand  $O(CH_2CH_2S)_2$  (odt) gives the six-coordinate compounds  $[V(odt)_2]$  and  $[V(NCMe)_6][VCl_2(odt)]_2$ , whose structures have been determined.<sup>83</sup> The tris-dithiolene complex  $[V(SCHCHS)_3]$  has  $D_{3h}$  symmetry and the compound has a delocalized electronic structure involving a spread of charge over the dithiolene ligands.<sup>102</sup>

A number of ligands having NSSN- and SNO-donor sets have been developed to bind nonoxo  $V^{IV}$ , using Schiff-base-type ligands or the tetradentate disulfide ligand 1,6-bis(*o*-pyridyl)-2,4, dithiahexane (NSSN) which forms the octahedral complex  $[VCl_2(NSSN)]$ .<sup>103</sup>

## 4.6 Vanadium(V) Coordination Complexes

### 4.6.1 Introduction

Many of the complexes of vanadium in their highest oxidation states contain oxygen and fluorine, and most contain at least one terminal oxygen atom. The  $d^0$  electronic configuration means that the complexes are diamagnetic, and their color is the result of charge-transfer transitions. Their diamagnetism has allowed extensive study by  $^{51}V$  NMR spectroscopy.<sup>13</sup> In aqueous solution, vanadium(V) forms a range of oxometalates, whose structures vary with concentration, temperature, and other conditions. Their study is well established and is beyond the scope of this survey, except to note the increasing use of NMR spectroscopy to examine the species that are present in solution.<sup>1,46</sup>

### 4.6.2 Halide Complexes

The structure of  $VF_5$  has been studied theoretically.<sup>104</sup> A number of hexafluorovanadates(V) such as  $K[VF_6]$  are well known.<sup>1</sup>

### 4.6.3 Oxo Complexes

**Neutral and Cationic Species Containing the  $VO^{3+}$  Unit.** This unit is found in the oxohalides  $VOX_3$  ( $X = F, Cl, Br$ ) and the nitrate,  $[VO(NO_3)_3]$ , that has a distorted pentagonal bipyramidal structure with overall  $C_s$  symmetry in the gas phase.<sup>105</sup> The oxochloride,  $VOCl_3$ , forms a number of addition complexes of the type  $[VOCl_3L_n]$  with monodentate ( $n = 1$ ) or bidentate ( $n = 2$ ) O-, S-, or N-donor ligands.<sup>1</sup>

$\text{VOCl}_3$  also undergoes a number of solvolysis reactions, mainly with alcohols, phenols, and carboxylic acids. Substitution products of the general type  $[\text{VOCl}_2(\text{OR})]$ ,  $[\text{VOCl}(\text{OR})_2]$ , and  $[\text{VO}(\text{OR})_3]$  are obtained. The nature of the product depends on the conditions used, especially the nature of the solvent and the stoichiometry of the reactants.<sup>1</sup> With bulky substituents, mononuclear complexes of this type can be crystallized and structurally characterized, for example  $[\text{VO}(\text{OC}_6\text{H}_3\text{Pr}_2^i-2,6)_3]$ , has a trigonal pyramidal structure.<sup>69</sup> A related compound is  $[\text{VO}\{\text{N}(\text{CH}_2\text{CH}_2\text{O})_3\}]$ , which has a trigonal pyramidal structure in the solid and in the organic solution, but a different structure in water.<sup>106</sup>

A large group of mononuclear complex cations of the type  $[\text{VO}(\text{L})]^+$  is known where L is commonly a Schiff-base,<sup>46,107</sup> or a hydroxamate. For example, the series  $[\text{VO}\{\text{salen}(5\text{-X})\}]^+$  (X = OMe, Me, or Br),<sup>88</sup> and  $[\text{VOClL}_2]$  (L = benzohydroxamate or N-phenylbenzohydroxamate).<sup>46</sup> They have the essentially square pyramidal geometry of their  $\text{V}^{\text{IV}}$  uncharged analogues (see Section 4.5.3). Dinuclear Schiff-base complexes of the type  $[(\text{VOL})_2]$  (L = Schiff base particularly with alkoxy substituents), have been obtained and have bis(alkoxy) bridging units.<sup>107</sup> Other examples of this type of complex use hydrazone ligands and include, as well as mononuclear complexes, binuclear, ligand-bridged compounds such as shown in (8).<sup>108</sup>

Other dinuclear complexes use bridging oxide<sup>109</sup> or fluoride<sup>88</sup> groups. Examples of this type with Schiff bases can be symmetric, as in the cation<sup>88</sup>  $[(\text{VOL})_2(\mu\text{-F})]^+$  or asymmetric as in  $[(\text{VOL}')(\mu\text{-O})(\text{VOL}'')]^{109}$  (L Schiff-base or similar ligand; L' and L'' = monodentate ligands). With certain polydentate Schiff-base ligands, dimeric complexes are formed that contain a  $\mu$ -oxo or  $\mu$ -OR ligand together with a bridge formed by a pendant phenolate group from the ligand. The  $\text{V}^{\text{IV}}\text{-V}^{\text{V}}$   $[\text{V}_2\text{O}_3]^+$  core in these compounds has the unpaired electron delocalized over the two vanadiums.<sup>109,110</sup>

**Anionic Species Containing the  $\text{VO}^{3+}$  Unit<sup>1</sup>.** Complex oxofluorides are well established, as are salts of  $[\text{VOCl}_4]^-$  and

$[\text{VOCl}_5]^{2-}$ . Anionic complexes with other ligands are rare, but a structurally characterized example is known, as shown in (9), and other examples with different ligands have been observed.<sup>92,111</sup>

**Species Containing the  $\text{VO}_2^+$  Unit.** Among the first examples of complexes shown to contain the *cis*-dioxo unit were  $[\text{VO}_2(\text{NO}_3)]$ , and  $[\text{PPh}_3\text{Me}][\text{VCl}_2\text{O}_2]$ . The oxo-groups were found to be *cis* to each other and to give rise to the expected two  $\text{V}=\text{O}$  IR bands found in the region of 960 and 970  $\text{cm}^{-1}$ .<sup>1</sup> Since that time, a range of mononuclear five-coordinated complexes showing these features has been prepared, most often with Schiff-base coligands, of general formula  $[\text{VO}_2\text{L}]$  (L = Schiff base with NNO- or  $\text{NO}_2$ -atom ligation).<sup>107,112</sup> Anionic monomeric complexes that have a six-coordinate vanadium such as ammonium dioxo(2-hydroxynaphthaldehyde semicarbazonato)vanadate(V) has been prepared<sup>1</sup> and the species  $[\text{VO}_2\text{L}]^-$  (L = maltolate or triethanolamine) have been observed in solution.<sup>46</sup>

Dimeric complexes of the  $\text{VO}_2^+$  group have single oxo-bridges giving a  $[\text{O}_2\text{V}-\text{O}-\text{VO}_2]$  core such as in  $[\text{L}_2\text{V}_2\text{O}_4(\mu\text{-O})]$  (L = 1,4,7-trimethyl-1,4,7-triazacyclononane),<sup>1</sup> or a rare type of dioxo bridge as seen in the compound shown in (10).<sup>113</sup> In this compound, the  $\mu\text{-O}$  distances are asymmetric, as indicated, the shorter being about 1.675 Å and the other around 2.27 Å.

A further type of dinuclear  $\text{VO}_2^+$  complex has terminal  $\text{V}=\text{O}$  groups but a pendant alkoxy group from a coligand on each vanadium gives rise to a bis( $\mu$ -alkoxy) system, as in  $[(\text{VO}_2\text{Ad})_2]^{2-}$  (Ad = adenosine).<sup>46,114</sup>

**Peroxo-Species.** Addition of aqueous  $\text{H}_2\text{O}_2$  to aqueous  $\text{V}^{\text{V}}$  results in the formation of various peroxo-complexes. In neutral or alkaline solutions, the yellow diperoxoorthovanadate ion,  $[\text{VO}_2(\text{O}_2)_2]^{3-}$ , is formed, whereas in acid solutions the red-brown peroxovanadium ion,  $[\text{V}(\text{O}_2)]^{3+}$ , is the main species present. Acidic salts such as  $\text{KH}_2[\text{VO}_2(\text{O}_2)_2]\cdot\text{H}_2\text{O}$  and  $(\text{NH}_4)_2\text{H}[\text{VO}_2(\text{O}_2)_2]\cdot n\text{H}_2\text{O}$  have been prepared and their IR spectra are characterized by the presence of a strong band at about 850  $\text{cm}^{-1}$ , probably associated with the O-O stretching vibration of the peroxo-group, which is coordinated

side-on to the metal (**11a**).<sup>1,46</sup> The peroxo-ligand can act as a terminal, side-on ligand, or in a ( $\mu$ -peroxy) mode (**11b**, **11c**).

Recent investigations of peroxo-complexes, especially those containing amino and carboxylate ligands, have been stimulated by interest in the vanadium bromoperoxidases and a wide range of peroxo-complexes has been prepared. Several reviews have been devoted to their chemistry and structures<sup>46,115</sup> and only a very brief outline is therefore given here. Types of complexes include those with: one peroxo-ligand  $[\text{VO}(\text{O}_2)(\text{L})]^-$  [ $\text{L}$  = tridentate, tetradentate or (bidentate)<sub>2</sub> ligand], two peroxo-ligands such as  $[\text{VO}(\text{O}_2)_2(\text{L})]^{2-}$  [ $\text{L}$  = monodentate or 1/2(bidentate ligand)], three peroxo-ligands,  $[\text{V}(\text{O}_2)_3(\text{L})]^{2-}$ , or four peroxo-ligands,  $[\text{V}(\text{O}_2)_4]^{3-}$ . Binuclear complexes are also known with  $\text{VO}(\text{O}_2)$  units bridged by one peroxo-group, or one or two such groups together with bridges formed by other ligands.<sup>46,115</sup>

#### 4.6.4 Nonoxo Complexes

There are few well-characterized examples of this type. Neutral tris(bidentate)  $\text{V}^{\text{V}}$  complexes of the type

$[\text{V}(\text{N}_3\text{S}_2)\text{L}(\text{L}')]$  ( $\text{L}'$  = bipy or phen;  $\text{L}$  = cat or dtbc) have been synthesized.<sup>1</sup> Complexes of the general type  $[\text{V}(\text{dtbc})_2\text{L}'][\text{SbF}_6]$ , prepared by oxidation  $[\text{V}(\text{dtbc})_2\text{L}']$  with  $\text{Ag}[\text{SbF}_6]$ , have also been investigated.<sup>1</sup>

#### 4.6.5 Nitrogen Ligands

Nitrido- and imido-complexes of  $\text{V}^{\text{V}}$  have drawn attention because of the interest in nitrogen fixation intermediates and in complexes that might provide catalyst precursors for polymerization of alkynes. Recent examples of such compounds are the six-coordinated cation<sup>116</sup>  $[\text{VN}(\text{acac})(1,4,7\text{-triazacyclononane})]^+$  and the six-coordinated complexes  $[\text{V}(\text{NR})(\text{L})]$  [ $\text{R}$  = alkyl or aryl;  $\text{L}$  =  $\text{N}(\text{CH}_2\text{CH}_2\text{S})_3^{3-}$  or  $\text{N}(\text{CH}_2\text{CH}_2\text{NR}')_3^{3-}$ ].<sup>82,98</sup> The related hydrazido(2-) complexes  $[\text{V}\{\text{N}(\text{CH}_2\text{CH}_2\text{S})_3\}(\text{NNR}_2)]$  ( $\text{R}_2$  =  $\text{CPh}_2$  or  $\text{C}_5\text{H}_{10}$ )<sup>117</sup> and the doubly nitrido-bridged dimer  $[\{\text{V}[\text{Me}_3\text{SiN}(\text{CH}_2\text{CH}_2\text{NSiMe}_3)_2\}]_2(\mu\text{-N})_2]$ <sup>118</sup> have also been structurally characterized.

#### 4.6.6 Sulfur and Selenium Ligands

A number of  $\text{V}^{\text{V}}$  complexes of the various types described in previous sections have S-donor ligands and a study has been made of vanadium complexes with cysteine and other biologically relevant S-donors<sup>46</sup> (see *Vanadium in Biology*). In this section, we draw attention to the known terminal sulfide and persulfide complexes. The complex anion  $[\text{VS}_2(\text{S}_2)\text{SPh}]^{2-}$  (**12**) has both sulfide and persulfide groups and two persulfide groups are found in  $[\text{NEt}_4][\text{VO}(\text{S}_2)_2(\text{bpy})]$ .<sup>119</sup> The terminal chalcogenide complexes  $[\text{V}(=\text{Y})\{\text{N}(\text{CH}_2\text{CH}_2\text{NR}')_3\}]$  ( $\text{Y}$  = S or Se,  $\text{R}'$  =  $\text{SiMe}_3$ ) have been prepared by reaction of  $[\text{V}\{\text{N}(\text{CH}_2\text{CH}_2\text{NR}')_3\}]$  with  $\text{S}_8$  or gray selenium,<sup>120</sup> and the four-coordinate  $\text{V}=\text{Se}$  complex  $[\text{V}(\text{Se})\{\text{Se}(\text{SiMe}_3)_3\}\text{N}(\text{SiMe}_3)_2]$  has been prepared.<sup>121</sup>

## 1 INTRODUCTION

Vanadium compounds exist in a variety of formal oxidation states from  $-3$  to  $+5$ . Their coordination number varies from 3 to 8. The stereochemistry depends on their oxidation state; V(II): 6-coordinate octahedral, V(III): 3–7-coordinate ( $V[CH(SiMe_3)_2]_3$ : 3-coordinate planar), V(IV): 4–6 or 8-coordinate ( $V(CH_2SiMe_3)_4$ : 4-coordinate tetrahedral,  $VO(acac)_2$ : 5-coordinate tetragonal), V(V): 4–7-coordinate ( $VOCl_3$ : 4-coordinate tetrahedral). Standard electrode potential in acidic aqueous solution is as follows:  $V^{2+} + 2e^- = V - 1.19$  V,  $V^{3+} + e^- = V^{2+} - 0.26$  V,  $VO^{2+} + 2H^+ + e^- = V^{3+} + H_2O + 0.36$  V,  $VO^{2+} + 4H^+ + 5e^- = V + 2H_2O - 0.25$  V. Generally speaking, vanadium compounds in a high oxidation state serve as oxidants. On the contrary, low-valent vanadium compounds are considered to be reductants. Paramagnetism is another interesting feature of some vanadium compounds.

The first organovanadium compound, which was discovered in 1953, is  $Cp_2VCl_2$ . Most organovanadium compounds are highly air and moisture sensitive, but not especially toxic except for the volatile carbonyl compounds. The organovanadium compounds are mostly subjected to interconversion via one-electron redox. Although vanadium compounds including vanadium(II), vanadium(III), vanadium(IV), oxovanadium(IV), and oxovanadium(V) are utilized in organic synthesis as reagents, catalysts, and polymerization catalysts (Ziegler–Natta catalysts, *see Ziegler–Natta Catalysts*),

the application of organovanadium compounds to synthetic reactions is rather limited.<sup>1–5</sup> The transformations are characterized by organometallic and/or redox-based reactions. This chapter describes the chemistry of organovanadium compounds mostly from synthetic viewpoints, which are classified depending on the coordination-binding mode.

## 2 $\eta^6$ - TO $\eta^8$ -ARENE AND RELATED COMPLEXES

( $\eta^6$ -Arene)vanadium(0) and related complexes bearing the corresponding aromatic hydrocarbons are one of the important classes of organovanadium compounds. Bis( $\eta^6$ -arene)vanadiums are synthesized by reductive aromatization of vanadium(III) or vanadium(IV) chloride with arenes in the presence of aluminum and aluminum trichloride, followed by hydrolysis of the generated cationic sandwich complexes.<sup>6,7</sup> Bis( $\eta^6$ -arene)vanadium(0) is a thermally stable 17-electron neutral sandwich complex. Thus obtained  $Mes_2V$  (**1**) undergoes further transformations as shown in Scheme 1; (**1**) is reduced with alkali metal to give the 18-electron complex (**2**).<sup>6</sup> The oxidation with silver tetraphenylborate leads to the vanadium(+I) cation (**3**).<sup>8</sup> A similar transformation is also achieved by treatment with bromo- or iodotriphenylmethane.<sup>9,10</sup> Generally, the six-membered rings are planar with the eclipsed conformation. On the contrary, almost staggered conformation is observed in the case of  $[Mes_2V]^-$ ,<sup>8</sup> in which the distance of V to the ring centroid is around 1.67 Å.

Hexacarbonylvanadium(0),  $V(CO)_6$ , which is a 17-electron, low-spin  $d^5$ , and paramagnetic complex, is reduced to the closed-shell 18-electron species,  $V(CO)_6^-$ , via one-electron reduction (*see Carbonyl Complexes of the Transition Metals*). This redox process is applied to the disproportionation reaction (*see Disproportionation*) in the presence of arene to give  $[V(\eta^6\text{-arene})(CO)_4][V(CO)_6]$  (**4**) (Scheme 2).<sup>11</sup>

Another route to bis( $\eta^6$ -arene)vanadium(0) compounds is the cocondensation of arenes with vaporized vanadium metal (*see Metal Vapor Synthesis of Transition Metal Compounds*).<sup>12,13</sup> On treatment with 1,3-cyclohexadiene and butyllithium, 15-electron vanadocene (**5**) is converted to 16-electron ( $\eta^6$ -benzene)( $\eta^5$ -cyclopentadienyl)vanadium(I) (**6**) (Scheme 3).<sup>14</sup> Use of potassium naphthalenide affords the corresponding naphthalene complex.

Various bis( $\eta^6$ -arene)vanadium(0) derivatives are prepared through substitution on the arene ring. Bis( $\eta^6$ -benzene)vanadium(0) (**7**) undergoes lithiation and coupling with electrophiles to give the substituted bis( $\eta^6$ -arene)vanadium compounds, like the silyl-bridged derivative (**8**) (Scheme 4).<sup>15</sup>

Triple-decker complexes (**9** and **10**, *see Triple-decker Sandwich*) are also accessible from  $CpV(\eta^3\text{-}C_3H_5)_2$  and 1,3-cyclohexadiene, or vanadocene and (naphthalene)Yb(THF)<sub>3</sub>, respectively.<sup>16</sup> The middle-deck

Scheme 1

Scheme 2

benzene can be replaced by mesitylene or toluene in the boiling aromatic.<sup>17,18</sup>

As  $\eta^7$ -complex analogs,  $\eta^7$ -Tp or tropylium vanadium complexes (11) and (12) are obtained from cycloheptatriene by treatment with  $\text{VCl}_4$  in the presence of *i*-PrMgBr (Scheme 5) or  $\text{CpV}(\text{CO})_4$ , respectively (Scheme 6).<sup>19-21</sup>

[7-7]Bitrovacene,  $\mu\text{-}\eta^7\text{:}\eta^7\text{-C}_{14}\text{H}_{12}[(\eta^5\text{-C}_5\text{H}_5)\text{V}_2]$  (13), is synthesized from  $\text{CpV}(\text{CO})_4$  and dicycloheptatriene. Inter-vanadium electro- and magneto-communication depends on

Scheme 3

Scheme 4

Scheme 5

the isomer (**14**) possessing the  $\mu\text{-}\eta^5\text{:}\eta^5\text{-fulvalenediyl}$  unit (Scheme 7).<sup>22</sup>

The complexation with the dianion of cyclooctatetraene leads to the formation of the mixed or half-sandwich complexes (see *Half-sandwich Complexes*) as shown in Scheme 8.<sup>23–25</sup> The coordination of the planar  $\eta^8\text{-cyclooctatetraene}^{(2-)}$  ligand is observed with  $\text{V}(\text{cot})_2$ . Generally, the distance between vanadium and ring centroid decreases with the increase of the ring size,  $\text{Cp} < \text{C}_6\text{H}_6 < \text{Tp} < \text{cot}$ .

Scheme 6

Scheme 7

Scheme 8

### 3 $\eta^5\text{-CYCLOPENTADIENYL AND RELATED COMPLEXES}$

This section describes the organovanadium compounds containing  $\eta^5\text{-cyclopentadienyl}$  (Cp) or substituted (Cp') ligands, which are classified into half-sandwich (see *Half-sandwich Complexes*), sandwich (see *Sandwich Compound*), bent sandwich (see *Bent Metallocenes*), and pseudo-triple decker derivatives. Cyclopentadienyl vanadium compounds are used for the synthesis of various vanadium compounds as mentioned above. Generally, the oxidation state of the cyclopentadienyl vanadium complexes is from  $-1$  to  $+5$ .

Bis( $\eta^5\text{-cyclopentadienyl}$ )vanadium (vanadocene, **5**, see *Metallocene Complexes*), which is the key derivative of this series, is characterized by a 15-electron species. Vanadocene is thermally stable under nitrogen but air sensitive. The

Scheme 9

vanadocenes are synthesized from  $\text{VCl}_3$  or  $\text{VCl}_2$  and alkali metal cyclopentadienide directly or after reduction (Scheme 9).<sup>26–35</sup> For example, the parent vanadocene (**5**) is obtained by reduction of vanadium(III) chloride with zinc and subsequent treatment with the cyclopentadienyl anion. Vanadium(III) chloride is directly converted to a similar complex (**15**) in the presence of sodium or lithium cyclopentadienide even in the absence of a reductant.  $\text{VCl}_4$  is also reduced to give vanadocene.<sup>36</sup>

The Cp rings of vanadocenes are usually in the staggered conformation.<sup>37</sup> Electrochemical properties in THF depend on the reversible one-electron reduction to  $[\text{Cp}_2\text{V}]^-$ . The oxidation process of  $\text{Cp}_2\text{V}$  involves reversible one-electron oxidation and successive irreversible one-electron oxidation.<sup>38</sup>

Sterically bulky vanadocene  $[\text{C}_5(i\text{-Pr})_n\text{H}_{5-n}]_2\text{V}$  is prepared by treatment of  $\text{VCl}_3$  or  $[\text{V}_2\text{Cl}_3]_2[\text{Zn}_2\text{Cl}_6]$  with the corresponding  $\text{K}[\text{C}_5(i\text{-Pr})_n\text{H}_{5-n}]$ .<sup>39</sup> The dinuclear cyclopentadienyl complex is also accessible. The fulvalenediyl complex (**16**) is obtained from  $\text{VCl}_2(\text{THF})_2$  and  $\text{C}_{10}\text{H}_6\text{Li}_2$  as shown in Scheme 10.<sup>40–42</sup>

Scheme 10

Scheme 11

Bis(alkylcyclopentadienyl)vanadium (**17**), which is synthesized as shown in Scheme 11, undergoes chlorination with  $\text{PCl}_3$  to give the corresponding blue monochloride (**18**) and green dichloride (**19**).<sup>43</sup>

Heteroatom ring substituted vanadocenes are rare except  $(\text{C}_5\text{H}_4\text{EMe}_3)_2\text{V}$  ( $\text{E} = \text{Si}, \text{Ge}, \text{Sn}$ ).<sup>44</sup>  $(\eta^5\text{-C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{NMe}_2)_2\text{V}$  is obtained by treatment with  $\text{Li}(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2\text{NMe}_2)$ .<sup>45</sup> The amino-functionalized vanadocene derivative (**20**) is also known.<sup>46</sup>

The bimetallic pentalene-bridged complex  $[\text{Cp}_2\text{V}]_2\text{Pn}$  (**21**,  $\text{Pn} = \text{C}_8\text{H}_6$ ) containing a V–V triple bond, in which the vanadium centers adopt a *syn*-coordination, is synthesized from  $\text{Li}_2\text{Pn} \cdot x\text{DME}$  ( $\text{DME} = 1,2\text{-dimethoxyethane}$ ) with 2 equiv of  $[\text{CpVCl} \cdot \text{THF}]_n$ .<sup>47</sup> The complex shows a high-spin/low-spin (*see High-spin & Low-spin Compounds*) equilibrium in both solution and solid states.

Since the vanadium center of vanadocenes is electron-deficient, various vanadium derivatives are formed by the attack with  $\text{PR}_3$ , CO, or unsaturated  $\pi$ -donating ligands.<sup>48</sup> This reaction provides a useful synthetic method for the synthesis of  $\eta^2$ -alkene complexes as described later. Thus formed  $\text{Cp}^*_2\text{V}(\text{CO})$  (**22**) is converted to the cyano derivative (**23**, see *Cyanide Complexes of the Transition Metals*) on treatment with the isocyanide (Scheme 12).  $(\eta^5\text{-C}_5\text{Me}_5)_2\text{V}$  is incubated with  $\text{O}_2$  at  $-78^\circ\text{C}$  to yield  $[(\mu\text{-}\eta^3\text{-C}_5\text{Me}_5\text{O}_3)\text{V}(\text{O})]_2$  via oxygen insertion into the carbon–vanadium bond.<sup>49</sup>

Various halides ( $\text{VCl}_4$ ,  $\text{VCl}_3$ , and  $\text{VBr}_2$ ) react with the 6-Me-*nido*-5,6,9- $\text{C}_3\text{B}_7\text{H}_9^-$  to give the paramagnetic air- and moisture-sensitive product,  $\text{V}(\text{Me-C}_3\text{B}_7\text{H}_9)_2$ , which is considered a tricarbadecaboranyl (see *Carborane*) analog of vanadocene. The complex is not oxidized with  $\text{Br}_2$  or  $\text{Ag}^+$ , indicating that the tricarbadecaboranyl anion stabilizes the metal in a low oxidation state.<sup>50</sup>

1,10-Phenanthroline-5,6-dione reacts with  $\text{Cp}_2\text{V}$  to form the O,O'-coordinated complex (**24**), which is subjected to further complexation with  $\text{M}'\text{Cl}_4$  ( $\text{M}' = \text{Ti}$  or  $\text{Hf}$ ) to give the bimetallic complex (**25**) (Scheme 13).<sup>51</sup> The opposite complexation process is also possible, affording a similar bimetallic complex (**26**) (Scheme 14).

Scheme 12

Scheme 13

Scheme 14

Scheme 15

Scheme 16

Vanadocene halide is another important analog that is transformed to various vanadocene derivatives. Vanadocene chloride is prepared from vanadium(III) chloride and thallium cyclopentadienide<sup>52</sup> or vanadocene and hydrogen chloride.<sup>53</sup> Vanadocene dihalide is similarly synthesized from vanadium(IV) halide via nucleophilic substitution.<sup>54</sup> Displacement of the chloro group results in functionalization as shown in Scheme 15.

Ring-bridged vanadocene halide and dihalide, (**28**) and (**29**) are obtained from bis(cyclopentadienyl)-substituted dianion (**27**) as shown in Scheme 16.<sup>55</sup> Furthermore,

Scheme 17

bis(cyclopenta-2,4-dienyl)dimethylsilanes or -germanes can be used as starting ligands.<sup>56</sup>

$\text{Cp}_2\text{V}(\text{OTf})_2$  (**30**), which is derived from vanadocene dichloride, forms the  $d^1$  vanadocene complex (**31**) with 1,10-phenanthroline or 2,2'-bipyridine (Scheme 17).<sup>57</sup> The two nitrogen atoms and centroids of the two cyclopentadienyl rings occupy a distorted tetrahedral geometry around  $\text{V}(\text{IV})$  center. Relatively low  $\text{V}(\text{IV})$ – $\text{V}(\text{III})$  reduction potential is observed.

A series of soluble vanadocene porphyrazines (**32**) and (**33**) are prepared.<sup>58</sup> The porphyrazine macrocycle mediates magnetic exchange interactions between metal ions bound to the periphery, separated by 14.5 Å.

The 14-electron  $[\text{Cp}_2\text{V}]^+$  cation (**34**) is isolated as an unsolvated species by one-electron oxidation of  $\text{Cp}_2\text{V}$  with  $[\text{Cp}_2\text{Fe}]^+$  (Scheme 18).<sup>59</sup>  $\text{Cp}_2\text{VCl}$  is prepared by treatment of the cation with  $[\text{PPN}]\text{Cl}$  ( $\text{PPN} = \text{bis}(\text{triphenylphosphine})\text{nitrogen}(+1)$ ). The reaction of vanadium hexacarbonyl with  $\text{Cp}_2\text{V}$  results in the formation of the  $\mu$ -isocarbonyl (see *Isocarbonyl Complexes*) derivative (**35**) as a transient species, which is converted to  $[\text{Cp}_2\text{V}(\text{CO})_2][\text{V}(\text{CO})_6]$  (**36**) on treatment with CO. Use of  $\text{Co}_2(\text{CO})_8$  instead of  $\text{V}(\text{CO})_6$  leads to  $\text{Cp}_2\text{VCo}(\text{CO})_4$  (**37**), which slowly decomposes to  $[\text{Cp}_2\text{V}(\text{CO})_2][\text{Co}(\text{CO})_4]$  (**38**). Ground-state electron transfer between TCNE and 16-electron  $\text{V}(\text{C}_5\text{R}_5)_2\text{Br}$  ( $\text{R} = \text{H}, \text{Me}$ ) is investigated.<sup>60</sup>

$\text{B} = 3,6\text{-butyloxybenzene}$   
 $\text{B} = (4\text{-}t\text{-butylphenyl})_2$

Methyl substitution on the cyclopentadienyl rings of  $\text{Cp}'\text{VCl}_2$  on the spermicidal activity is investigated.<sup>61</sup> The corresponding oxo compound,  $\text{Cp}'\text{V}(\text{O})\text{Cl}_2$ , does not show the activity.  $\text{V}(\eta^5\text{-C}_5\text{H}_5)_2((\text{C}_2\text{H}_5)_2\text{NCS}_2)(\text{BF}_4)$  is reported to be a potential and stable spermicidal compound.<sup>62</sup>  $[\text{Cp}_2\text{V}(\text{acac})](\text{CF}_3\text{SO}_3)$  is known as a dual-function anticancer agent with antiangiogenic and antimitotic properties.<sup>63</sup>

$\text{CpV}(\text{CO})_4$ , which is a typical half-sandwich complex, is prepared by reduction of vanadocene with sodium or potassium under carbon monoxide. Another route to  $\text{CpV}(\text{CO})_4$  involves the direct reaction of hexacarbonylvanadium(0) with cyclopentadiene. The Cp ring is disordered between staggered and eclipsed conformations.<sup>64</sup> The distance between the centroid and vanadium is 1.9–2.0 Å.

Replacement of the carbonyl ligand affords the corresponding vanadium derivatives.<sup>65–67</sup> The partially phosphine-substituted complex (**39**) is obtained by treatment of phosphine-stabilized  $\text{VCl}_3$  with cyclopentadienide, followed by reductive carbonylation (Scheme 19).<sup>68</sup> A variety of cyclopentadienylvanadium halides in the oxidation state 2–5 are synthesized from  $\text{Cp}_2\text{V}$  or  $\text{CpV}(\text{CO})_4$ .<sup>69–75</sup> For example, the reaction of  $\text{CpV}(\text{CO})_4$  with halogen or oxygen provides the corresponding oxidized complexes as shown in Scheme 20. Use of thiols or chalcogens results in the formation of the corresponding substituted complexes (**40**)<sup>76</sup> and (**41**)<sup>77</sup> (Scheme 21).

Scheme 18

Scheme 19

Scheme 20

Scheme 21

A fulvene is used for the preparation of the substituted  $\eta^5$ -cyclopentadienylvanadium(I) complexes (42) and (43) (Scheme 22).<sup>78,79</sup>

Dimerization or cyclotrimerization is performed by reduction of  $(\text{C}_5\text{Me}_4\text{R})\text{VX}_3$  (44,  $\text{R} = \text{Me}, \text{Et}$ ) with Na or treatment of  $\text{VX}_3\text{L}_3$  ( $\text{L} = \text{THF}, \text{THT}$ ) with  $(\text{C}_5\text{Me}_4\text{R})\text{SnBu}_3$  to give the vanadium(III) halides,  $(\eta^5\text{-C}_5\text{Me}_4\text{R})_2\text{V}_2(\mu\text{-Br})_4$  (45, paramagnetic, V–V distance, 2.565 Å) and  $(\eta^5\text{-C}_5\text{Me}_4\text{R})_3\text{V}_3(\mu\text{-Cl})_6$  (46, spin-frustrated antiferromagnetic (see *Antiferromagnetism*), V–V distance, 3.373 Å) (Scheme 23).<sup>80</sup> Unusual difference in V–V distance and magnetochemistry is observed. Halogenation leads to the reformation of (44).

Reduction of  $[(\eta\text{-C}_5\text{Me}_5)\text{VCl}(\mu\text{-N})]_2$  (47) with sodium amalgam in toluene, or with lithium nitride or magnesium in tetrahydrofuran, gives diamagnetic  $[(\eta^5\text{-C}_5\text{Me}_5)\text{V}(\mu_3\text{-N})]_4$  (48) (Scheme 24).<sup>81</sup>

#### 4 $\eta^3$ -ALLYL AND RELATED COMPLEXES

$\eta^3$ -Allylvanadium complexes (see *Allyl Complexes*) are synthesized by allylation with Grignard reagents as shown in Scheme 25.<sup>82</sup> Another synthetic route lies in the allylation of a vanadium anionic species with allylic chloride.<sup>83</sup> Codimerization of vanadium-coordinated diphenylacetylene (tolane) and 1,3-butadiene affords the allyl complex (49) (Scheme 26).<sup>84</sup>

The  $\eta^3$ -1-azaallyl complex (51) is formed by [2 + 2] cycloaddition of (50) with alkyne. The metallacycle intermediate is considered to be involved in this transformation (Scheme 27).<sup>85</sup>

Scheme 22

Scheme 23

Scheme 25

Three-electron donor ligands like  $\eta^2$ -acyl ones are also described here. The  $\eta^2$ -CH<sub>2</sub>O complex (**52**) is formed by treatment of Cp<sub>2</sub>V with paraformaldehyde. Various vanadium compounds are available from (**52**) as shown in Scheme 28.<sup>86</sup>

Use of an acyl chloride permits the transformation from the V(0) compound (**53**) to the  $\eta^2$ -acyl complex (**54**) (Scheme 29).<sup>87-89</sup> The iminoacyl group of (**55**) is also coordinated in the  $\eta^2$ -mode (Scheme 30).<sup>90</sup>

A variety of vanadium carbonyl compounds are obtained from [V(CO)<sub>6</sub>]<sup>-</sup>. Use of 1-chloropenta-2,4-diene under photoirradiation leads to V( $\eta^5$ -C<sub>5</sub>H<sub>7</sub>)(CO)<sub>4</sub>. The  $\eta^2$ -bonded acyl complex is formed similarly by photoinduced substitution with benzoyl chloride.<sup>91</sup> The  $\eta^2$ -C,O coordination mode is

Scheme 24

Scheme 26

Scheme 27

Scheme 28

Scheme 29

observed with the ketene complex (56), which undergoes the attack of butyllithium and silylation to give the silyl enol ether (57) (Scheme 31).<sup>92</sup>

Scheme 30

Scheme 31

## 5 $\eta^2$ -ALKYNE OR ALKENE COMPLEXES

Side-on coordination of an unsaturated ligand, alkyne or alkene, provides the corresponding complexes in the  $\eta^2$ -mode. Vanadium-alkyne complexes like  $\text{Cp}_2\text{V}(\text{RC}\equiv\text{CR})$  ( $\text{R} = \text{COOMe}, \text{CF}_3$ ) are formed by treatment of vanadocene with alkynes as shown in Scheme 32.<sup>93–96</sup>  $(\eta^2\text{-Alkyne})(\eta^5\text{-cyclopentadienyl})\text{bis}(\text{trimethylphosphine})\text{vanadium(I)}$  (59) is obtained by reductive coordination of  $\text{CpVCl}_2(\text{PMe}_3)_2$  (58) with alkyne (Scheme 33).<sup>84,97</sup>

Use of  $\text{CpV}(\text{CO})_4$  under photoirradiation affords  $\text{CpV}(\eta^2\text{-C}_6\text{F}_5\text{C}\equiv\text{CC}_6\text{F}_5)(\text{CO})_2$  (Scheme 34).<sup>98</sup> Cyclooligomerization of diphenylacetylene with  $\text{Cp}_2\text{V}_2(\text{CO})_5$  affords the  $\eta^4$ -cyclobutadiene complex (60),  $\text{V}(\text{C}_4\text{Ph}_4)\text{Cp}(\text{CO})_2$  (Scheme 35).<sup>99</sup> The above-mentioned side-on monomeric complex is obtained with the more basic alkyne like dimethylacetylene.

Scheme 32

Scheme 33

Scheme 34

Scheme 35

Scheme 36

The homobimetallic vanadium  $d^1-d^1$  complex (see **Dinuclear Organometallic Cluster Complexes**),  $(\text{Cp}_2\text{V})_2(1-2\eta:3-4\eta\text{-RC}=\text{C}=\text{C}=\text{CR})$  is formed by treatment of  $\text{Cp}_2\text{V}$  with  $\text{Me}_3\text{SiC}\equiv\text{C}-\text{C}\equiv\text{C}-\text{CSiMe}_3$  or  $\text{Ph}_2\text{PC}\equiv\text{C}-\text{C}\equiv\text{C}-\text{CPh}_2$ .<sup>100</sup> Antiferromagnetic moments depend on the bridging spacer. The  $d^2-d^2$  homobimetallic complex (62) is derived from  $\text{Me}_3\text{SiC}\equiv\text{C}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{CSiMe}_3$  (61) as shown in Scheme 36.<sup>101</sup>  $\text{Cp}_2\text{V}$  migration is observed with further complexation of  $\text{Cp}_2\text{V}(3-4\eta\text{-}t\text{-BuC}\equiv\text{C}-\text{C}_2-\text{C}\equiv\text{CC}\equiv\text{CBu-}t)$  to give the dimetallic complex  $(\text{Cp}_2\text{V})_2(1-2\eta:7-8\eta\text{-}t\text{-BuC}\equiv\text{C}-\text{C}_2-\text{C}\equiv\text{CC}\equiv\text{CBu-}t)$ .<sup>102</sup>

Bis(alkynyl)phosphane (63) similarly reacts with  $\text{Cp}_2\text{V}$  to give the vanadacyclopropene phosphane (64), which is converted to the alkenyl-alkynyl phosphane (65) on treatment with HCl in toluene (Scheme 37).<sup>103</sup>

$(\text{C}_5\text{H}_4\text{R})_2\text{Zr}(\text{C}\equiv\text{CPh})_2$  (66,  $\text{R} = \text{Me}, t\text{-Bu}$ ) is transformed to  $\text{Cp}_2\text{V}(\mu\text{-}\eta^2:\eta^4\text{-butadiyne})\text{ZrCp}'_2$  (67) in the presence of  $\text{Cp}_2\text{V}$  via the zirconacyclocumulene intermediate as shown in Scheme 38.<sup>104</sup>

The alkyne complex (68) reacts with two equivalents of ethene to give the *s-cis*-3,4-(*E*)-diphenyl-1,3-hexadiene complex (69) as shown in Scheme 39. Use of 2-butyne leads to the metallacycle (70) via bis(alkyne) complex.<sup>84</sup> The bicyclic vanadacyclopentatriene complex (71) is formed from 1,7-nonadiyne.

$\text{Cp}_2\text{V}(\eta^2\text{-alkene})$  is synthesized by treatment of vanadocene with alkene bearing an electron-withdrawing group.<sup>93,105,106</sup> The reaction of vanadocene with dimethyl fumarate or dimethyl maleate leads to the formation of the same complex, bis( $\eta^5\text{-cyclopentadienyl}$ )( $\eta^2\text{-dimethyl fumarate}$ )vanadium (72), via isomerization (Scheme 40).

$\text{CpV}(\eta^2\text{-ethene})(\text{PMe}_3)_2$  (74) is obtained as a green paramagnetic complex via the carbon-carbon bond cleavage of the 1,4-divanabutane intermediate,  $\text{Cp}(\text{PMe}_3)_2\text{V}(\text{CH}_2)_4\text{V}(\text{PMe}_3)_2\text{Cp}$ , which is produced by reduction of dichloro( $\eta^5\text{-cyclopentadienyl}$ )bis(trimethylphosphine)vanadium(II) (73) with Na/Hg and successive treatment with 1,4-di-Grignard compound (Scheme 41).<sup>84,107</sup> Reaction of (74) with carbon monoxide or diphenylacetylene provides the ligand exchange complexes (75) and (76), respectively. The vanadolactone (77) is formed on treatment with carbon dioxide.

The  $\eta^4\text{-vinylketene}$  complex is obtained by photoirradiation of  $\text{CpV}(\text{CO})_4$  with triphenylcyclopropene via CO insertion.<sup>99</sup>

Scheme 37

Scheme 38

Scheme 39

Scheme 40

as catalysts for metathesis polymerization. Although vanadium complexes are of importance in the field of polymer chemistry, only few carbene complexes have been isolated so far.

The acylvanadium complex (78) is converted to the Fischer type (*see Fischer-type Carbene Complexes*) vanadium complex (79) on treatment with  $\text{Me}_3\text{O}^+\text{BF}_4^-$  (Scheme 42).<sup>108</sup>

The N-substituted carbene analog is formed from  $\text{Na}_2[\text{VCp}(\text{CO})_3]$  and iminium chloride (80) as shown in

## 6 CARBENE COMPLEXES

Carbene complexes, in which the carbenes generally bind end-on to the metals through  $\sigma$  donor bond and  $\pi$  bond, are recognized as one of the key organometallics and used especially

Scheme 42

Scheme 41

Scheme 43

Scheme 43.<sup>109</sup> The Fischer-type (*see Fischer-type Carbene Complexes*) vanadium complexes are prepared by treatment of (butadiene)hafnocene (**81**) or (butadiene)zirconocene with  $\text{CpV}(\text{CO})_4$  (Scheme 44). The equilibrium mixture reacts with cyclopentanone to give the adduct complex (**82**).<sup>110–112</sup>

Thermolysis of  $(\eta^5\text{-cyclopentadienyl})\text{bis}(\text{neopentyl})(\text{trimethylphosphine})\text{vanadium(I)}$  (**82**) in the presence of 1,2-bis(dimethylphosphino)ethane leads to the formation of the Schrock-type (*see Schrock-type Carbene Complexes*) alkylidene vanadium complex (**83**), which is supported by X-ray crystallographic analysis (Scheme 45).<sup>113,114</sup> The imido vanadium complex (**84**) is converted to the corresponding alkylidene complex (**86**) on treatment with benzylidene(triphenyl)phosphorane (**85**) via substitution of the phosphine ligand (Scheme 46).<sup>115</sup>

Silylation of  $\text{Na}[\text{V}(\text{CO})_2(\text{Me}_2\text{PCH}_2\text{CH}_2\text{PMe}_2)_2]$  affords the vanadium carbyne complex (*see Carbyne Complexes*),  $\text{V}(\text{COSiPh}_3)(\text{CO})(\text{Me}_2\text{PCH}_2\text{CH}_2\text{PMe}_2)_2$ , which is supposed to be a precursor complex for the formation of a  $\eta^2$ -acetylene

Scheme 45

Scheme 44

complex via reductive C–C coupling (*see Reductive C–C Coupling*).<sup>116</sup>

Isocyanide ligands (*see Isocyanide Ligands*) are comparable to carbon monoxide in their  $\sigma$ -donor and  $\pi$ -acceptor ability. Isocyanide complexes (**87**) are formed by ligand exchange of  $\text{CpV}(\text{CO})_4$  with an isocyanide, which is facilitated by palladium(II) catalyst (Scheme 47).<sup>117</sup> The ligand substitution reaction is also observed with  $[\text{V}(\text{CO})_6]^-$  to give the corresponding vanadium isocyanide complex (**88**) with the oxidation state  $-1$  (Scheme 48).<sup>118–121</sup> The ligand exchange reaction proceeds via oxidation to give the homoleptic (*see Homoleptic Compound*) vanadium(II) complex (**89**) as shown in Scheme 49.<sup>122,123</sup>

Scheme 46

Scheme 47

Scheme 48

Scheme 49

## 7 $\sigma$ -BONDED ORGANO- OR HYDRIDOVANADIUM COMPLEXES

The  $\sigma$ -bonded organovanadium compounds are generally unstable, but a wide variety of usage has been developed in organic reaction. The synthetic routes to organovanadium compounds depend on the oxidation state of vanadium. For medium- and high-valent compounds, V–X is replaced by an organic group. Alkyl or aryl vanadium(III) or (IV) compounds (**90**) are synthesized by the reaction of VCl<sub>3</sub> or VCl<sub>4</sub>, respectively, with organolithium compounds or Grignard reagents, in which 2,4,6-Me<sub>3</sub>C<sub>6</sub>H<sub>2</sub>-, Me<sub>3</sub>SiCH<sub>2</sub>-, and C<sub>6</sub>F<sub>5</sub>-substituted derivatives are used (Scheme 50).<sup>124–130</sup> The nitrogen-bridged organovanadium(III) complex (**91**) is obtained when the reaction is carried out under nitrogen (Scheme 51).<sup>131</sup> Thus formed complex (**91**) undergoes oxidation with styrene oxide to the corresponding oxo complex (**92**).

Cyclopentadienyl-substituted vanadium(III) compound (**93**) is also allowed to undergo the substitution reaction to give the  $\sigma$ -alkyl,  $\sigma$ -alkynyl, or  $\sigma$ -aryl complexes (**94**, Scheme 52).<sup>82,132–137</sup> [NBu<sub>4</sub>][V(C<sub>6</sub>Cl<sub>5</sub>)<sub>4</sub>], which is prepared

Scheme 50

Scheme 52

Scheme 53

Scheme 54

Scheme 51

from VCl<sub>3</sub>(THF)<sub>3</sub> and C<sub>6</sub>Cl<sub>5</sub>Li, is isolated and characterized as a homoleptic, tetrahedral, and paramagnetic d<sup>2</sup> complex.<sup>138</sup>

In the case of low-valent vanadium compounds, metathesis or hydrovanadation is used for the synthesis of organovanadium compounds. Treatment of vanadocene with halomethane results in the formation of the methyl-substituted halo-vanadocene (**95**) (Scheme 53).<sup>139</sup> The dianion species (**96**) is similarly used for this purpose (Scheme 54).<sup>140</sup>

Coordination numbers of organovanadium compounds are 3 to 6 as exemplified by pseudotetrahedral (Cp<sub>2</sub>V(C≡C*t*-Bu)<sub>2</sub>),<sup>136</sup> OVMes<sub>3</sub>,<sup>126</sup> square pyramidal (VPh<sub>4</sub>),<sup>141</sup> and octahedral [(LiOEt<sub>2</sub>)<sub>4</sub>VPh<sub>6</sub>].<sup>142</sup> The V(II) and V(III) compounds in a high-spin configuration (*see High-spin & Low-spin Compounds*) exhibit normal Curie–Weiss behavior.<sup>143</sup> Reaction modes vary disproportionation, symproportionation, ligand coupling, and insertion as shown in Scheme 55.

Scheme 55

A variety of synthetic transformations have been developed by using vanadium compounds or intermediates. Cp-substituted vanadiums are used in catalytic polymerization, which involves organovanadium intermediates.<sup>144</sup>

Isomerization of alkenes is catalyzed by bis( $\eta^3$ -allyl)( $\eta^5$ -cyclopentadienyl)vanadium(IV).<sup>145</sup> Cyclohexene undergoes catalytic stereoselective aerobic oxidation with CpV(CO)<sub>4</sub>.<sup>146</sup> Reductive coupling (*see Reductive Coupling*) of aldehydes and aldimines is catalyzed by a Cp-substituted vanadium compound in the presence of a chlorosilane and zinc or aluminum.<sup>147–151</sup> Vanadocene or bis( $\eta^5$ -cyclopentadienyl)dimethylvanadium(IV) catalyzes the synthesis of 1,2-diphenyldisilane and 1,2,3-triphenyltrisilane from phenylsilane.<sup>152</sup>

Organovanadium compounds exhibit unique reactivity on the basis of the redox characteristics of the vanadium. For example, treatment of VCl<sub>3</sub> in THF with a stoichiometric amount of *n*- or *s*-alkylmagnesium halides affords alkanes, alkenes, and dimers.<sup>153</sup> The organovanadium compounds generated

in situ couple chemoselectively with acid chlorides or allyl halides.<sup>154</sup> A related reaction with aldehydes yields coupled ketones via oxidative nucleophilic addition (Scheme 56).<sup>155,156</sup>

Direct geminal allylation of propiophenone with allyl bromide proceeds in the presence of VCl<sub>3</sub>(THF)<sub>3</sub>/Zn or VCl<sub>2</sub>(TMEDA)<sub>2</sub>/Zn.<sup>157</sup> This deoxygenative transformation is performed by the oxophilicity of low-valent vanadium (Scheme 57). Successive treatment of propiophenone with a Grignard reagent, VCl<sub>2</sub>(TMEDA)<sub>2</sub>, and allylic bromide results in geminal carbon–carbon bond formation at the carbonyl carbon (Scheme 58). Homocoupling, rather than allylation, of the alkoxyvanadium intermediate (**97**) occurs in the presence of a catalytic amount of molecular oxygen.<sup>158</sup> Allylic vanadium and oxovanadium compounds are characterized.<sup>159</sup>

Scheme 56

Scheme 57

Scheme 58

Scheme 59

$\text{VO}(\text{acac})_2$  reacts with  $N,N'$ -diphenylformamidine (**(98)**) to give oxobis[6-(phenylamino)hexane-2,4-dionato-O,O']vanadium(IV) (**(99)**) via substitution onto methyl group of the acetylacetonate ligand (Scheme 59).<sup>160</sup>

Insertion into a carbon–vanadium bond provides a variety of useful synthetic strategies. For example, the methylvanadium complex (**(100)**), obtained from  $\text{CpVCl}_2(\text{PMe}_3)_2$  and  $\text{MeLi}$ , rapidly inserts carbon monoxide (*see CO Insertion*) to give acetone and  $\text{CpV}(\text{CO})_2(\text{PMe}_3)_2$  (Scheme 60).<sup>161</sup>

*t*-Butyl isocyanide likewise inserts into three carbon–vanadium bonds of  $[\text{V}(\text{Mes})_3(\text{THF})]$  to give the tris( $\eta^2$ -iminoacyl) complex (**(101)**). When the complex (**(101)**) is exposed to air, (**(101)**) is converted to the corresponding amide (**(102)**), while its exposure to water produces the imine (**(103)**) through hydrolysis (Scheme 61).<sup>162</sup>

The reaction of  $\text{VCl}_3(\text{THF})_3$  with  $(\text{Me}_3\text{Si})_2\text{NLi}$  leads to the dimeric complex (**(104)**) via C–H  $\sigma$ -bond metathesis (*see  $\sigma$ -Bond Metathesis*) of a trimethylsilyl group (Scheme 62).

Scheme 60

The dinuclear enolate complex (**(105)**) is then formed by treatment of (**(104)**) with carbon monoxide, which inserts into the vanadium–carbon bonds.<sup>163</sup>

Hydrovanadation is an effective route to the organovanadium compounds as shown in Scheme 63.<sup>164–166</sup> Hexacarbonylhydridovanadium,  $\text{VH}(\text{CO})_6$ , is a thermally unstable,

Scheme 61

Scheme 62

neutral complex with 18-electron configuration. Ligand exchange with the phosphine ligand provides a more stable complex.<sup>167</sup> Treatment of  $\text{V}(\text{CO})_6^-$  with silica gel leads to a similar hydridovanadium complex (*see Hydrides*).<sup>168–170</sup>

The air-sensitive Cp-substituted hydridovanadium complex is obtained by hydrogenolysis of the corresponding methyl derivative.<sup>53</sup> The corresponding anionic compound is obtained by reduction of  $\text{CpV}(\text{CO})_4$  with sodium and protonation with water (Scheme 64).<sup>140</sup> Thus obtained  $[\text{CpVH}(\text{CO})_3]^-$  (**106**) is a useful one-electron reductant to reduce bromo- and iodoalkanes, bromoalkenes, and arylbromides in THF. Furthermore, acid chlorides are reduced to the aldehydes. A similar reduction with (**106**) is performed by using phase-transfer conditions in the presence of tetrabutylammonium hydrogen sulfate. Nitro compounds and organic halides are reduced under these conditions.

Complexation of the oxo group of  $\text{VO}(\text{CH}_2\text{SiMe}_3)_n$  ( $\text{OSiPh}_3$ )<sub>3–n</sub> ( $n = 0–3$ ) with  $\text{Al}(\text{CH}_2\text{SiMe}_3)_3$  facilitates the insertion of ethylene into the carbon–vanadium bond by reducing the degree of  $\pi$ -donation from the oxo ligand. This type of interaction is important in olefin polymerization.<sup>171</sup> The oxovanadium(V)-catalyzed oxidation of benzyltin compounds occurs under oxygen atmosphere to afford the aromatic aldehydes (ketones) and/or carboxylic acids. Oxidative ligand coupling of organoaluminums, organoborons, organozincs, and their -ate complexes is achieved by treatment with oxovanadium(V) compound, leading to the formation of the C,C-coupled adducts.<sup>172</sup> The reaction is considered to proceed via electron-transfer process or transmetalation (*see Transmetalation*) to generate organovanadium species.

The 1,2,4-azaphosphavanada(V)cyclobutane (**108**), which is obtained by cyclization of the imidovanadium(V) compound (**107**) with phosphalkyne, reacts with alkyne to give

Scheme 63

Scheme 64

Scheme 65

the 1*H*-1,2-azaphosphole (**109**) via reductive elimination, (see *Reductive Elimination*), (Scheme 65).<sup>173,174</sup>

## 8 CONCLUSION

The investigation on the chemistry of organovanadium compounds is rather limited probably because of the difficulty in the characterization and isolation, but their properties and reactivities appear to be of potential as materials, medicine, reagents, and catalysts. Functionalization or design of organic moieties and redox properties will provide a variety of organovanadium compounds, which may open the door of new vanadium chemistry.

## Abbreviations

bzacH = 1-phenyl-1,3-butanedione; dikeH =  $\beta$ -diketone;  
dpmH = 2,2,6,6-tetramethylheptanedione (dipivaloylmethane); HIm = imidazole; Hpz = pyrazole; pico = 2-picolylamine.

## 1 INTRODUCTION

There are a vast number of O-donor ligands, ranging from simple naturally occurring ligands such as water, which have been studied for many decades, to artificial systems such as the crown ethers and calixarenes, which are a relatively recent development. Exhaustive coverage of all these ligands is not possible here, and hence the discussion is divided into categories of the most widely studied systems. The aim of the article is to demonstrate the nature of the complexes formed by the ligands and some of the chemistry involved in obtaining them.

## 2 WATER, HYDROXIDE, AND OXIDE

### 2.1 Introduction

A large proportion of inorganic chemistry takes place in aqueous solution, and hence the nature of the species formed

when a metal ion is dissolved in water is of great importance, and has been the subject of study for many years. This leads to consideration of water, hydroxide, and oxide as ligands. These are discussed individually below, but it is appropriate to briefly consider the relationship between the three species.

Deprotonation of the parent aqua ions,  $[M(OH_2)_x]^{n+}$ , gives rise to hydroxo and then oxo complexes, and consequently the nature of the species present in solution is strongly dependant on pH. The acidity of the aqua ions varies enormously with the metal ion, with an approximate correlation with electrostatic considerations. Thus, higher charge density of the metal ion is often associated with greater acidity of the aqua ion. Such trends are not reliable, however, since properties such as high oxidizing power and 'softness' (see *Hard & Soft Acids and Bases*) are generally associated with strongly acidic aqua ions. It follows that hydroxo and oxo ligands tend to be associated with highly charged metal ions, while only oxo ligands, which are very difficult to oxidize, are found with the highest oxidation states, in species such as  $MnO_4^-$  and  $CrO_4^{2-}$ . Exceptions to this can be found in the larger actinide cations, where water molecules are found coordinated to metal ions in oxidation states of 5+ and 6+, although the complexes also include oxo ligands; one example is the complex ion  $[UO_2(OH_2)_5]^{2+}$ . Various combinations of aqua, hydroxo, and oxo ligands can be found, including species containing all three (most commonly with the vanadyl (see *Vanadium: Inorganic & Coordination Chemistry*), and uranyl (see *Actinides: Inorganic & Coordination Chemistry*) cations).

Finally, it is important to note that, while  $H_2O$  is a relatively poor bridging ligand, both hydroxo and oxo ligands readily act as bridges between metal atoms, giving rise to polynuclear species, which are not discussed in detail here (see *Polyoxometalates*).

### 2.2 Aqua Complexes

Discrete  $[M(OH_2)_x]^{n+}$  species are found in the hydrates of many metal salts where the anion is a poor ligand, such as  $ClO_4^-$ ,  $PF_6^-$ ,  $BF_4^-$ , and so on. In many cases, particularly for the first-row transition metals but also other cations such as  $Mg^{2+}$ ,  $Al^{3+}$ , and  $In^{3+}$ , hexaaqua ions are formed with an octahedral arrangement of water O atoms about the metal atom. The larger lanthanide and actinide ions generally form octa- or nonaaqua ions, although octahedral hexaaqua ions have been found in  $Ln(ClO_4)_3 \cdot 6H_2O$ .<sup>1</sup> Water is a relatively poor bridging ligand, although a search of the Cambridge Structural Database reveals ~500 examples including main group and transition metal complexes.<sup>2</sup>

The nature of ions in aqueous solution has been studied using a wide variety of techniques, including X ray and neutron diffraction, and quasielastic neutron scattering, NMR, IR, and UV spectroscopies. The ions are generally considered to have primary and secondary hydration spheres, although there is relatively little quantitative information available concerning the second sphere in solution.<sup>3</sup> The rate of exchange of the

H<sub>2</sub>O molecules in the hydration spheres with the bulk H<sub>2</sub>O solvent varies by many orders of magnitude depending on the metal ion.<sup>3</sup> This, combined with the use of many different experimental techniques, has resulted in discrepancies in the literature, particularly for metal ions with a weakly bound, rapidly exchanging hydration sphere. The Na<sup>+</sup> cation, for example, has had quoted values for the primary solvation number ranging from 2 to 13, although a value close to six is generally accepted.<sup>4</sup>

Metals that form relatively stable aqua ions in solution have generally been well characterized. The hydration numbers of the transition metals, for example, have commonly been found to be six, consistent with the results of solid-state studies of crystalline hydrates. Exceptions include Ag<sup>+</sup>, which has a hydration number of four, and Cu<sup>2+</sup>, which has been found to have four short M–O interactions and two longer ones, consistent with a Jahn–Teller distortion (*see Jahn–Teller Effect*) of the complex. The hydration numbers of the lanthanide ions in solution have been the subject of many investigations and some controversy; recent results suggest a decrease from nine to eight across the series from La<sup>3+</sup> to Lu<sup>3+</sup>.<sup>4</sup>

### 2.3 Hydroxo Complexes

The hydroxide ion assumes bridging coordination modes more often than water. Double  $\mu_2$ -hydroxide bridges (2) are the most common, although single hydroxide bridges (1) have been known for some time in complexes such as [(H<sub>3</sub>N)<sub>5</sub>Co( $\mu$ -OH)Co(NH<sub>3</sub>)<sub>5</sub>]<sup>5+</sup>. Both double and single hydroxide bridges may be supported by another bridging ligand. Triple hydroxide bridges are relatively rare and quadruple hydroxide bridges (3) have only been observed to date linking zirconium porphyrin moieties.<sup>5</sup>  $\mu_3$ -Hydroxide (4) is also relatively rare, occurring most frequently in cubane type structures (5), in species such as [Cr<sub>4</sub>(OH)<sub>4</sub>]<sup>8+</sup> and [Ni<sub>4</sub>(OH)<sub>4</sub>]<sup>4+</sup>.<sup>6</sup>

Hydrated hydroxide metal complexes can also form a hydrogen-bonded H<sub>3</sub>O<sub>2</sub><sup>−</sup> bridging moiety, which has been structurally characterized in single bridged<sup>7</sup> and double bridged species; [(pico)<sub>2</sub>Cr(H<sub>3</sub>O<sub>2</sub>)<sub>2</sub>Cr(pico)<sub>2</sub>] (6),<sup>8</sup> is an example of the latter. These bridges have been formulated as discrete H<sub>3</sub>O<sub>2</sub><sup>−</sup> and alternatively as H<sub>2</sub>O/OH<sup>−</sup> bridges;

theoretical studies suggest the bridging H atom should be increasingly asymmetrically positioned as the O···O distance increases.<sup>9</sup>

### 2.4 Oxo Complexes

The multiply bonded oxo group, found in transition metal complexes such as UO<sub>2</sub><sup>2+</sup>, MnO<sub>4</sub><sup>−</sup>, and OsO<sub>4</sub>, is usually terminal, although very asymmetric  $\mu_2$ -oxide bridges have been observed, suggesting an M = O → M bridge.

Single, double, and triple  $\mu_2$ -oxo bridges are known, although single bridges are the most common. The M–O–M angle about a single oxo bridge can vary from 140 to 180°, depending mainly on steric and electronic factors. Double and triple bridges are most commonly found in **Polyoxometalates**.

$\mu_3$ -Oxo bridges are well known and can form planar or pyramidal M<sub>3</sub>–O units, usually with equal M–O distances. Molybdenum(IV) in aqueous solutions forms Mo<sub>3</sub>O<sub>4</sub><sup>4+</sup> (7), for example, which has three  $\mu_2$ -oxo bridges and a pyramidal  $\mu_3$ -oxo bridge.<sup>10</sup> Trimetallic, triangular metal carboxylates contain a triangular  $\mu_3$ -oxo ligand and are known for a number of transition metals (*see* Section 6.1).  $\mu_4$ -Oxide is less common, but is found in a number of carboxylates where the oxo ligand is surrounded by a tetrahedral arrangement of M atoms, which are also linked by the carboxylate ligands (8). The Zn<sub>4</sub>O(carboxylate)<sub>6</sub> unit, for example, has been used as a building block in constructing impressive metal-organic frameworks with highly porous structures.<sup>11</sup> (*See also Oxides: Solid-state Chemistry*).

### 3 ALKOXIDES AND ARYLOXIDES

Metal alkoxides and aryloxides, of the general formula  $M(OR)_x$ , can be considered as derived from the alcohol  $ROH$  by replacement of the hydroxylic hydrogen atom by the metal.<sup>12</sup> These complexes have been known for many years;  $Ti(OEt)_4$  was prepared in 1924 by Bischoff and Adkins,<sup>13</sup> and the synthesis was attempted as early as 1875 by Demarçay<sup>14</sup> although pure product was apparently not obtained. Potential technological applications have resulted in increased activity in this area in recent years (see *Sol-Gel Synthesis of Solids*).<sup>15,16</sup>

#### 3.1 Structure and Bonding

Although usually considered to be a one-electron ligand, alkoxide and aryloxy groups can assume a number of modes of coordination (Figure 1), with the M–O distances decreasing in the order  $M-OR (\mu_3) > (\mu_2) > \text{terminal}$ . Shorter terminal M–O distances are found to be associated with larger M–O–C angles; for example, the Zr–O–C angle in  $[ZrCl_4(OMe)(MeOH)]$  is  $171.4^\circ$ , compatible with a Zr–O triple bond, with the alkoxide ligand acting as a three-electron donor. Shorter M–O bonds and larger M–O–C angles appear to be associated with increasing electron deficiency of the metal.<sup>17</sup>

Most alkoxides with simple R groups are polymeric or oligomeric to an extent that satisfies the coordination of the metal.<sup>18</sup> Some common types of small oligomeric structures are shown in Figure 2. Although a large body of data has been collected on these systems, it is still difficult to predict which structure will be formed by a certain combination of M and RO. Factors that appear to influence the structure include the size and oxidation state of the metal atom, the steric bulk of the alkyl or aryl group, and the  $d^n$  configuration (for the transition elements). The introduction of very bulky alkyl or aryl groups favors the formation of lower oligomers or monomeric species, often with unusually low coordination numbers. A decrease in the extent of oligomerization usually results in an increase in the volatility of the metal alkoxide.

#### 3.2 Synthesis

In some cases, metal alkoxides and aryloxides can be obtained simply by direct reaction of the appropriate alcohol

**Figure 1** Coordination modes of alkoxide and aryloxy ligands

**Figure 2** Some structural types for small oligomeric metal alkoxides

or phenol with the bulk metal (equation 1). The method is limited by the low  $pK_a$  of alcohols and most phenols to the more electropositive elements. Group 1 metals react readily in this way, while group 2, 3, and the lanthanide metals require the presence of a catalyst, such as iodine or a mercury(II) salt, for the reaction to take place. Electrochemical synthesis using a sacrificial anode of the required metal is applicable to a greater range of metals, but this method has not been widely exploited.

A more common approach to the synthesis of metal alkoxides and aryloxides is to make use of a metal halide. This method is particularly effective for the less electropositive elements such as B, Si, and P, where the reaction readily goes to completion (equation 2). Analogous reactions of the halide derivatives of more electropositive elements, such as the transition metals, often give products containing both halide and alkoxide ligands, as shown in equation (3). The acidity of the alcohol also influences the course of the reaction; phenols, for example, are more acidic than alcohols and are more likely to effect complete substitution of the halide ligands (compare equations 3 and 4). The problem of incomplete substitution can be overcome by carrying out the reaction of the metal halide and alcohol in the presence of a base. Anhydrous ammonia is often employed as the proton acceptor, with the precipitation of ammonium chloride forcing the reaction to completion (equation 5). This is probably the most widely used method of synthesizing homoleptic alkoxides and aryloxides.

The reaction of metal halides with an alkoxide or aryloxy (most commonly an alkali metal alkoxide), can result in metathetic exchange to give the required complex (equation 6). Such reactions can also result in the formation of heterometallic species (such as  $\text{NaZr}_2(\text{OR})_4$ ); this can be a problem when homometallic alkoxides are desired, but it is an important route to heterometallic alkoxides and aryloxides. The nature of the product can be influenced by the alkali metal, the alkoxide ligand, and the relative amounts of the reactants.<sup>19</sup>

Metal diamides are useful starting materials in the synthesis of these compounds, particularly for the early transition metals where available routes to the metal alkoxides are limited (equation 7). R in equation (7) is often the bulky  $\text{SiMe}_3$  group;  $\text{N}(\text{SiMe}_3)_2$  is known to be a good leaving group, and the by-product  $\text{HN}(\text{SiMe}_3)_2$  is reasonably volatile. The use of less bulky dialkylamides such as  $\text{M}(\text{NMe}_2)_n$  can lead to complications such as adduct formation where the dimethylamine formed is coordinated to the metal center. Other convenient starting materials include metal hydrides and alkyls, which react similarly, to give volatile by-products (hydrogen or an alkane) and the metal alkoxide. Finally, alcohol interchange reactions make use of metal alkoxides to produce new alkoxides as shown in equation (8). The order of reactivity of the attacking alcohol tends to be primary > secondary > tertiary. Interchange reactions are particularly useful in the synthesis of phenoxides owing to the higher acidity and lower volatility of phenols relative to alcohols.

It is important to note that efforts to synthesize metal alkoxides and aryloxides (particularly lanthanide and actinide complexes) have sometimes produced unexpected products, incorporating halide or oxide ligands, for example. As a result, some early literature may contain incorrect formulations.<sup>12,15,17</sup>

### 3.3 Reactions of Alkoxides and Aryloxides

Protonolysis reactions of alkoxides and aryloxides are common; one example is hydrolysis of the metal alkoxide, giving metal oxide with elimination of the alcohol. Although the aim is often to avoid such a reaction, it is of great interest in the deposition of high-purity metal oxides, which are used in areas such as optoelectronics, high  $T_c$  superconductors, and advanced ceramics.<sup>15</sup>

Other protonolysis reactions include reactions with carboxylic acids to give metal carboxylates (see Section 6) and with  $\beta$ -diketones to give the metal  $\beta$ -diketonates (see Section 4), as shown in equations (9) and (10), respectively.

Hydrogenolysis can provide a route to metal hydrides; one example is shown in equation (11) (see *Hydride Complexes of the Transition Metals*).

Insertion reactions involving metal alkoxides are also known. For example, carbon dioxide is known to react with some metal alkoxides as shown in equation (12). The formation of a bidentate ligand is a significant thermodynamic driving force for some of these reactions. The isoelectronic aryl and alkyl isocyanates and carbodiimides can react similarly. Insertion reactions involving alkenes and carbon monoxide are known for platinum alkoxides.

### 3.4 Catecholates, *o*-Quinone, and *o*-Semiquinone Ligands

These three ligands are related by the addition or removal of electrons as shown in equation (13). A metal–quinone chelate ring can be considered to have three potential isoelectronic forms, depending on the distribution of formal charge between the metal and ligand. The form that predominates can depend, for example, on the other ligands attached to the metal, as shown for the copper complexes (9) and (10).<sup>19</sup>

Just as the free ligand can be interconverted by redox processes, so can the corresponding metal complexes. For

example, tris(semiquinone)chromium(III) can undergo a stepwise three-electron oxidation to the tris(benzoquinone) complex, or a stepwise three-electron reduction to the tris(catecholato)chromium(III) trianion. Intermediate, mixed-ligand species have also been characterized.<sup>20</sup>

*o*-Quinone and semiquinone complexes are generally prepared under anhydrous conditions, either directly by combination of the ligand and a metal salt or complex (such as a metal carbonyl complex), or by electrochemical procedures from catecholate complexes. Catecholate complexes are more readily synthesized, and are known for a wide range of metal ions. Characterization of these complexes as quinone, semiquinone, or catecholate, using X-ray diffraction, EPR (see *Electron Paramagnetic Resonance*), NMR, and magnetic methods (see *Magnetochemistry*), is generally straightforward, but complications can arise in systems where there is a small separation between the energies of the metal and quinone electronic levels. This can result in an equilibrium between redox isomers with differing charge distributions as shown in equation (14). The term valence tautomerism has been applied to this phenomenon.<sup>19</sup> Changes in the charge distribution can be induced by changes in temperature, light irradiation or altering the structure of the coligands. These systems have potential applications as sensors and switches.<sup>21</sup>

Much of the interest in these complexes arises from their relevance to biological systems. For example, the binding site for iron in some siderophores is found to include three catecholate groups (see *Iron Transport: Siderophores*). This has led to a great deal of work using catecholate-based systems as sequestering agents for metals of biological and environmental importance.<sup>22,23</sup> Quinone–iron interactions are also important in photosynthesis and respiration processes

(see *Photosynthesis*). Finally, it should be noted that *p*-quinones and the related mono- and dianions, by nature of the geometry of the molecule, often form a bridge between metal atoms.

## 4 $\beta$ -DIKETONES AND RELATED LIGANDS

2,4-Pentanedione (acac) and related  $\beta$ -dicarbonyl compounds are an extremely important class of ligands that have been studied widely for many years. In general,  $\beta$ -dicarbonyl compounds exist as mixtures of tautomeric keto and enol forms (equation 15). These compounds are usually easily deprotonated to form monoanions, which form the basis for a large class of coordination compounds, encompassing virtually every element. In addition, coordination compounds of the dianions and trianions of  $\beta$ -diketones have been observed, as well as complexes of the neutral molecules.<sup>24,25</sup>

### 4.1 Structure and Bonding

The  $\beta$ -diketones are a versatile class of ligand with many known modes of coordination, some of which are shown in Figure 3. O,O'-chelation (**11**) of the monoanion is by far the most common mode, being found for almost all of the metallic and metalloid elements. Compounds of the stoichiometry M(dike)<sub>3</sub> and M(dike)<sub>2</sub> are the most common. The former generally have an almost octahedral distribution of the six oxygen atoms when M is a main group or transition metal. These compounds have been used extensively in studies of the mechanism of the racemization of trischelate complexes.

**Figure 3** Examples of some of the coordination modes known for  $\beta$ -diketonate anions

$\beta$ -Diketone complexes of the lanthanides tend to adopt higher coordination numbers, often crystallizing as hydrates.

Complexes with the composition  $M(\text{dike})_2$  usually exist as oligomers, so that the metal atoms are coordinatively saturated. For example, the acetylacetonate complexes of Ni, Zn, and  $\text{Mn}^{\text{II}}$  exist in the solid state as trimers of varying structure, with bridging  $\beta$ -diketonate groups (20).<sup>26</sup> The extent of oligomerization varies with the metal cation:  $\text{Cu}^{\text{II}}$  forms a monomer, while  $\text{Co}^{\text{II}}$  forms a tetrameric structure. Substituting the terminal methyl groups with larger substituents favors the formation of the monomer, although these are often solvated to give five- or six-coordinate complexes. O-O'-chelation in combination with bridging (12) is thus quite common, whereas the purely bridging mode of coordination (13) is rare, but was first observed in lanthanide complexes such as  $\text{Er}_8\text{O}(\text{OH})_{12}(\text{dpm})_{10}$ , which has a complex structure where eight of the dpm ligands are bidentate chelate, and the remaining two are purely bridging.

(20)  $[\text{Mn}(\text{acac})_2]_3$

The monoanions of  $\beta$ -dicarbonyl compounds also form organometallic species, usually involving the central carbon atom in the M-C bond (14). Such species are known for a number of metals, particularly those of the platinum group. This mode of binding leaves the two carbonyl oxygen atoms free, allowing the formation of bimetallic species (15).  $\eta^3$ -Allylic (16) and terminal (17) carbon bonding have also been observed.

Dianions of  $\beta$ -diketones are also known to form metal complexes, but are much less common than systems containing the monoanion. Such complexes usually involve main group elements or members of the platinum group, and may be coordinated to the O atoms (18) or terminal C-atoms (19).<sup>25,27</sup>

## 4.2 Synthesis

Metal  $\beta$ -diketonates are generally synthesized from the neutral  $\beta$ -diketones and the appropriate bulk metal or metal salt are synthesized in solvents such as water, dioxane, ethanol, or neat diketone. The use of the bulk metal is limited to the more electropositive elements such as the group 1 and 2 metals, although the method is more widely applicable with more acidic  $\beta$ -diketones, such as those with perfluoroalkyl substituents. Electrochemical syntheses

of some acac complexes have been described, using the appropriate metal anode.

More common is the use of a metal salt, such as halide, hydroxide, oxide, sulfate, carboxylate, and so on. A base can also be added, to convert the  $\beta$ -diketone to the  $\beta$ -ketoenolate anion, which usually has greater solubility in aqueous media.

Metal alkoxides and alkyls are useful starting materials, particularly for the preparation of some unsolvated  $\beta$ -diketonates that require anhydrous conditions (see Section 3.3). Addition of  $\beta$ -diketonate ligands to metal alkoxides has also been used to produce heteroleptic metal complexes that are less reactive than the homoleptic metal alkoxides; this simplifies the use of such complexes in chemical vapor deposition applications.<sup>16</sup>

## 4.3 Reactions of $\beta$ -diketonates

Metal  $\beta$ -diketonates, particularly acetylacetonates, will undergo electrophilic substitution at the central methine carbon atom in a similar way to aromatic compounds. Known reactions of this sort include bromination, nitration, acylation, and the Mannich reaction.

Hydrolysis (the reverse of the preparative reaction) and other exchange reactions of the metal  $\beta$ -diketonates have been studied in some detail in order to probe the mechanisms of inorganic substitution reactions. As mentioned in Section 4.1, there has been intense study of the intramolecular rearrangements of  $M(\text{dike})_3$  complexes. Decomposition of metal  $\beta$ -diketonate complexes to give high-purity metals or metal oxides is of technological importance.

Metal  $\beta$ -diketonates are often coordinatively unsaturated (see *Coordinative Saturation & Unsaturation*) and will therefore react with Lewis bases to form complexes. For example, the trimer  $[\text{Ni}(\text{acac})_2]_3$  will react with Lewis bases such as water or pyridine to form monomeric *trans*- $[\text{Ni}(\text{acac})_2\text{L}_2]$ . The formation of weak complexes with lanthanide  $\beta$ -diketonates is critical in their use as NMR shift reagents.

## 4.4 Complexes of Neutral $\beta$ -diketones

A number of complexes of neutral  $\beta$ -diketones are known, although such complexes are generally not very stable. They can be synthesized by addition of the  $\beta$ -diketone to a simple metal salt or coordinatively unsaturated metal complex, by controlled hydrolysis of a metal  $\beta$ -diketonate, or by displacement of a weakly bound neutral ligand by the  $\beta$ -diketone.

O,O'-chelation (21) of acacH has been found in  $\text{NiBr}_2(\text{acacH})_2$  and  $[\text{Ni}(\text{acacH})_2(\text{H}_2\text{O})_2](\text{ClO}_4)_2$ . O-unidentate coordination of the enol form (22) has been structurally characterized in  $\text{MnBr}_2(\text{acacH})_2$  and  $[\text{ReCl}(\text{CO})_3(\text{bzacH})]_2$ .  $\eta^2(\text{C},\text{C}')$  coordination of the enol (23) has been implicated by NMR and IR studies of the platinum complex  $[\text{PtCl}(\text{acac})(\text{acacH})]$ .<sup>28</sup>

#### 4.5 Polyketonate and Bis- $\beta$ -diketonate Complexes

1,3,5-Triketones and similar polyketones exhibit keto–enol tautomerism and have been found to coordinate to one or more metal atoms (**24**). Such complexes can bring metal atoms in close proximity, resulting in interesting magnetic properties (see *Magnetism of Transition Metal Ions*).

A series of bis- $\beta$ -diketones, linked by the methine carbon atoms, have been found to form ‘cofacial’ dicopper(II) species (**25**) which have cavities of varying sizes, depending on the nature of the linking group.<sup>29</sup> The inclusion of various small molecules within the cavity has been investigated. Another interesting system involves bis- $\beta$ -diketones linked at the terminal carbon atoms by glycol ether linkages of varying lengths, which will transport alkali metal atoms through a membrane only when complexed to a copper(II) cation (**26**).<sup>30</sup>

#### 4.6 Tropolonates

Although formally an  $\alpha$ -diketone, tropolone gives rise to a monoanion (equation 16) with coordination chemistry similar to that of the  $\beta$ -diketonate anions. The tropolonate ion forms a five-membered chelate ring, which has a smaller Bite Angle (see *Bite Angle*) than  $\beta$ -diketonate anions. This feature, in combination with its rigid planar nature, makes the tropolonate ion suitable for the formation of complexes

with high coordination numbers at the central metal ion. For example, the thorium(IV) and uranium(IV) complex anions  $M(\text{trop})_5^-$  are 10 coordinate. Another result of the small bite angle of this ligand is that tritropolonato metal complexes are considerably distorted from octahedral geometry.<sup>31</sup>

### 5 OXOANIONS

Oxoanions (see *Oxoanion*) include species such as  $\text{SO}_4^{2-}$ ,  $\text{CrO}_4^{2-}$ , and so on. They consist of a central element, which is often nonmetallic but can also be metallic, to which is bound a number of terminal oxygen atoms.<sup>32</sup> Oxoanions where the central element is carbon, such as  $\text{CO}_3^{2-}$ , and related substituted species such as carboxylates,  $\text{RCO}_2^-$ , exhibit somewhat different coordination chemistry to other oxoanions and are discussed in Section 6.

#### 5.1 Structure and Bonding

The terminal oxygen atom in an oxoanion has three lone pairs, and can therefore, in principle, coordinate to up to three metal atoms. The maximum coordination number (i.e. the number of metals to which the oxoanion is bound) for an oxoanion  $[\text{XO}_n]^{m-}$  is therefore  $3n$ . In practice, the great majority of mononuclear oxoanions have  $n$  in the range 2 to 6, and  $m$  in the range 1 to 6, with coordination numbers of four or less.

There are a large number of possible coordination modes for the various oxoanions, in association with varying numbers of metal atoms. It should be noted that a significant problem in defining coordination modes is the length of an M–O bond. It has been suggested that, where the M–O distances differ by less than  $0.7 \text{ \AA}$ , there is a significant interaction between the M atom and both O atoms.<sup>32</sup> Longer bond distances are indicated by dashed lines in the following diagrams. Consideration of the bond lengths within the oxoanion can be useful in describing the bonding, since most X–O bonds in oxoanions have some double bond character and therefore the X–O distances for the coordinated O atoms are expected to increase, while the noncoordinated X–O distances decrease, relative to the free oxoanion. Unfortunately, the changes in the geometry of oxoanions upon coordination are usually small and are difficult to determine accurately.

### 5.1.1 Coordination Modes of Triangular Oxoanions

The most widely studied of these oxoanions is the nitrate anion,  $\text{NO}_3^-$ . Some of the known coordination modes of this anion are shown in Figure 4(a). The most common is the symmetrical bidentate mode (27). Examples of unidentate (28) and asymmetrical bidentate (29) coordination modes are also quite plentiful. The most common bridging coordination mode for these and all oxoanions is the symmetrical *syn-syn* mode involving two oxygen atoms of the oxoanion (30). The other modes (31–33) shown in Figure 4 are relatively rare. The  $\eta^1:\mu_3$  mode with a single oxygen bridging three metal atoms (32) has been observed in a tetranuclear manganese complex.<sup>33</sup> The  $\eta^3:\mu_3$  mode (33) has been found in  $[\text{Cu}_3(\text{OH})(\text{pz})_3(\text{Hpz})_2(\text{O}_3\text{N})(\text{ONO}_2)] \cdot \text{H}_2\text{O}$ <sup>34</sup> and more recently in a bis- $\beta$ -diketonate complex, where the nitrate anion links octanuclear copper clusters.<sup>31</sup>

### 5.1.2 Coordination Modes of Bent Oxoanions

Examples of this group of oxoanions include  $\text{NO}_2^-$ ,  $\text{ClO}_2^-$ , and  $\text{H}_2\text{PO}_2^-$ , although most of the available data concern the nitrite anion and hence the discussion will center on complexes of this anion.<sup>35</sup> Some of the known coordination modes are shown in Figure 4(b) (34–39). Monodentate coordination predominates, through the terminal O atoms to give nitrito complexes (34), and through the central N atom to give nitro complexes (35). The most common bridging mode is the N–O

mode (36), although others are known, combining bidentate O chelate plus monodentate O or N coordination (37 and 38, respectively).

### 5.1.3 Coordination Modes of Tetrahedral Oxoanions

Examples of oxoanions of this geometry are numerous, and include  $\text{SO}_4^{2-}$ ,  $\text{SeO}_4^{2-}$ ,  $\text{AsO}_4^{3-}$ ,  $\text{PO}_4^{3-}$ ,  $\text{SiO}_4^{4-}$ ,  $\text{VO}_4^{3-}$ ,  $\text{CrO}_4^{2-}$ , and  $\text{ReO}_4^-$ . Tetrahedral oxoanions are found to coordinate to up to 12 metal atoms, although simple unidentate (40), bidentate chelate (41), and bidentate (and higher) bridging (42) coordination modes are more common.<sup>32</sup> The tridentate triply-bridging mode (43) is an interesting example of coordination to a metal cluster.<sup>36</sup> The number of examples known decreases rapidly for coordination numbers above three.

### 5.1.4 Coordination Modes of Pyramidal Oxoanions

The most widely studied of these oxoanions is  $\text{SO}_3^-$ ; others include  $\text{HPO}_3^{2-}$  and  $\text{IO}_3^-$ . The coordination modes known are similar to those of the tetrahedral oxoanions (Figure 4c), with additional modes involving bonding to the central heteroatom.

## 5.2 Spectroscopy

The IR spectra of the free oxoanions are well characterized, with the modes of vibration being determined by the number of atoms and the symmetry of the ion. The changes in symmetry and bond order that take place upon coordination can result in significant changes in the IR spectrum, allowing differentiation of the free and complexed species.<sup>28</sup> For example, the IR spectrum of free  $\text{NO}_3^-$  ion has absorptions at  $\sim 1390$ , 830, and  $720\text{ cm}^{-1}$ , whereas coordinated nitrate groups, which have lower symmetry, exhibit six absorptions. While it is usually relatively easy to distinguish between free and complexed oxoanions, it is often much more difficult to determine the mode of coordination (e.g. distinguishing between mono- and bidentate coordination or between bidentate chelate and bridging modes), and hence it is often necessary to obtain crystallographic structure determinations to determine the coordination modes of these anions with certainty. Other spectroscopic techniques that have been employed include EXAFS (see *Extended X-ray Absorption Fine Structure*),  $^{17}\text{O}$  NMR, and X-ray powder diffraction.<sup>37</sup>

## 5.3 Synthesis

Oxoanions usually have weak donor properties relative to water and nitrogen donors, and thus the properties of coordination complexes of these anions are extremely solvent dependent. For example, the  $\text{ClO}_4^-$  ion is generally considered to be a weakly coordinating anion in aqueous solution, and

**Figure 4** Some coordination modes of the (a) nitrate anion, (b) nitrite anion, and (c) tetrahedral anions

yet in nonaqueous solvents such as  $\text{HClO}_4$  or  $\text{Cl}_2\text{O}_6$ ,  $\text{ClO}_4^-$  forms complexes with a variety of metals clearly involving anion coordination to the metal ions. Stronger ligands, such as the  $\text{NO}_3^-$  anion, are known to form complexes even in aqueous solution. The octahedral periodate and tellurate anions readily form stable complexes in aqueous solutions.<sup>38</sup> Hence, synthesis of oxoanion complexes is generally straightforward, provided water or other strong ligands are excluded.

## 6 CARBOXYLATE AND RELATED SPECIES

### 6.1 Monocarboxylates

Monocarboxylates are an attractive class of ligand for the coordination chemist; they bind to metal atoms in a variety of ways giving, in many instances, complexes with interesting properties, and they are readily available.<sup>37</sup> Figure 5(a) shows some of the known modes of coordination (44–51). Unidentate (44) and symmetrical chelate coordination (45) modes are well established, with the unidentate mode being more commonly observed. The presence of unidentate carboxylate can be established by IR spectroscopy, by virtue of the inequivalence of the two C–O bonds in the coordinated anion,<sup>28</sup> although care must be exercised since the environment of the free carboxylate O atom, and even sample preparation, can influence the IR spectrum.

The most common bridging mode of coordination is *syn-syn* (47). The nature of the metal–metal interactions in such systems has been the subject of much study, with interaction varying from the relatively weak in dimeric  $\text{Cu}^{\text{II}}$  complexes, to strongly M–M bonded species such as  $\text{Mo}_2(\text{O}_2\text{CR})_4$ , which contains a formal quadruple bond. The two systems that have been most studied are the bimetallic (52) and trimetallic (53) complexes, often referred to as ‘paddle-wheel’ and ‘triangular’ complexes respectively.<sup>39</sup> These structural motifs have been widely utilized in the construction of coordination polymers and metal-organic frameworks.<sup>11,40</sup>

**Figure 5** Some coordination modes of (a) monocarboxylate anions, (b) dicarboxylate anions, (c) the carbonate anion, (d) the dianion of squaric acid, and (e) the dianion of croconic acid

Distinguishing the various bridging modes of the carboxylates has been carried out using IR and NMR

spectroscopies and magnetic measurements, although support from X-ray structure determinations has been vital in obtaining definitive information on these complexes.

Carboxylate complexes are often synthesized by refluxing the acid with the metal salts (such as carbonate, sulfate, oxide, etc.), or by reaction of the sodium or silver salt of the acid with the metal halide. Insertion of CO<sub>2</sub> into  $\sigma$ -bonded organotransition metal species has also been used to generate carboxylate complexes, as has exchange reactions with metal alkoxides (see Section 3.3).

## 6.2 Dicarboxylates

The coordination chemistry of the dicarboxylates is somewhat different to that of the monocarboxylates, since the close proximity of the carboxylate groups allows coordination involving one O atom of each. The simplest and most intensively studied of these compounds is oxalic acid (ethanedioic acid), complexes of which are found in nature (e.g. in the mineral humboldtine). Some coordination modes for this acid are shown in Figure 5(b). Unlike monocarboxylates, chelate coordination is favored over the unidentate mode (54). Of the two modes of chelate coordination, the formation of the larger chelate ring (57) is generally formed in preference to the four-membered chelate ring (56), with the latter becoming more common in higher members of the dicarboxylate series, where the two carboxylate groups are further apart.

There are many possible bridging modes (55,58,59) for the dicarboxylic acids with the bis-bidentate bridging mode (59) being the most common. The bridging mode (58) is very rare for the shorter dicarboxylates,<sup>35</sup> but is widely observed with the longer more rigid dicarboxylates used in some metal-organic frameworks.<sup>11,40</sup> X-ray diffraction is the most reliable method of determining the coordination mode of the dicarboxylates, although chemical methods have been useful; for example, protonation reactions can reveal the presence of uncoordinated carboxylate groups, since these are easily protonated unlike the coordinated groups. Metal interactions in dicarboxylate complexes, particularly oxalate complexes, have been of interest, with copper complexes being the most studied. The magnetic properties of oxalate-bridged Cu<sup>II</sup> dimers [LCu(ox)CuL']<sup>2+</sup> has been found to be highly variable, and strongly influenced by the nature of the terminal ligands L and L'.<sup>41</sup> Dicarboxylate complexes are usually synthesized by reaction of an aqueous solution of the alkali metal salt of the dicarboxylate with a metal halide, or by reduction of a metal salt by the dicarboxylic acid. For example, oxalic acid readily reduces iron oxides to form the iron(II) complex.

## 6.3 Carbonates

The carbonate ion is a component of many naturally occurring minerals and is important in biological systems and

thus it has been widely studied. The coordination chemistry of this anion is well developed and the common unidentate (60) and bidentate chelate (61) coordination modes have been observed, as well as a wide variety of quite complex bridging modes (62–67). Vibrational spectroscopy is quite useful in distinguishing free carbonate from the nonbridging coordination modes, since coordination results in a change in the symmetry of the ion.<sup>28</sup> The bridging modes can usually only be determined via structure determination studies.

Carbonate complexes are usually synthesized from carbonate or bicarbonate anions in alkaline aqueous solution. The reaction of metal hydroxides with carbon dioxide is another route to carbonate complexes. Other methods include the oxidation of metal carbonyl complexes (equation 17), and the oxidation of metal salts in the presence of carbon dioxide.

## 6.4 Cyclic Oxocarbon Acids

Of the known cyclic oxocarbon acids, the systems based on squaric (68) and croconic (69) acids have been most widely studied.<sup>42</sup> The loss of two protons from these acids gives rise to aromatic dianions as shown in equations (18) and (19), and these can coordinate to metal anions in a variety of ways. Unidentate coordination (70,77) is known for both systems but is not common. Simple bidentate chelate coordination (78) is also relatively uncommon but is observed in a number of croconate complexes. The squarate anion adopts this mode only with larger cations, such as the group 2 and lanthanide metals, and then only in association with additional bridging interactions. Bridging coordination modes dominate the chemistry of these anions, some of which are shown here (71–76), (79–81). The various modes of coordination can usually be distinguished by IR spectroscopy, and the use of <sup>13</sup>C NMR spectroscopy has also been investigated.

The magnetic properties of complexes of these anions have been studied, particularly copper(II) complexes, and have been compared with the results obtained with analogous oxalato complexes;<sup>41</sup> the squarato and croconato bridges are

able to transmit magnetic effects between metal atoms, but are not as efficient as the oxalato bridge.<sup>42</sup>

Squarato and croconato metal complexes are usually synthesized by mixing an aqueous solution of the dipotassium salt of the acid with a metal ion, although nonaqueous solvents have also been employed.

## 6.5 Carbamates

Carbamate ( $R_2NCO_2^-$ ) complexes are similar electronically and structurally to monocarboxylate complexes, although they are not as accessible synthetically and are generally less stable.<sup>43</sup> Unidentate, chelate, and bridging coordination modes have been observed, although the number of bridging modes found to date is less than that known for carboxylates. *Syn-syn* bridging is the most common, and bimetallic ‘paddlewheel’ type structures (53) are known.

Carbamate complexes are synthesized by carbonation of metal dialkylamides (equation 20), or by reaction of the appropriate amine, carbon dioxide, and a metal halide (equation 21). In both cases, it has been suggested that the reaction involves combination of the amine and carbon dioxide to form the carbamate anion, followed by anion exchange.<sup>43</sup>

## 6.6 Hydroxycarboxylic Acids

Many hydroxycarboxylic acids are naturally occurring, and their coordination chemistry is of importance in biological processes.<sup>44</sup> These complexes also have uses in many other areas such as analytical chemistry, electroplating processes, and pharmacology. The most widely studied aliphatic hydroxy acids are the lower members of the 2-hydroxyalkanoic acids, while studies of aromatic hydroxy acids have often centered on salicylic acid. A number of these acids contain one or more chiral carbon centers, and hence complexes of these acids have been useful in studying chiroptical properties such as the Cotton Effect (see *Cotton Effect*).

A common feature of the coordination chemistry is the formation of a five-membered chelate ring involving one O atom of the carboxylate group, and the O atom of the hydroxyl group, which may or may not retain the hydroxylic H atom (82). The O atoms may also bridge to other metal atoms.

## 6.7 Hydroxamates

Hydroxamic acid<sup>45</sup> exists in two tautomeric forms (83) and (84). Spectroscopic evidence suggests that metal complexes are generally best described by the structure (85), as a hydroxamide group rather than a hydroxyoxime. Hydroxamic acids are of importance in analytical chemistry, having been widely used as metal precipitants and as colorimetric reagents. Another interesting aspect is the presence of hydroxamate binding groups in siderophores (see *Iron Transport: Siderophores*).<sup>23</sup>

# 7 MACROCYCLIC O-DONOR LIGANDS

## 7.1 Introduction

Unlike most of the O-donor ligands discussed in this article, the study of synthetic macrocycles (see *Macrocyclic Ligands*) such as Crown Ethers (see *Crown Ethers*), Cryptands & Cryptates (see *Cryptands & Cryptates*), and the calixarenes (see *Calixarenes*) is a relatively recent development. The beginnings of this area are perhaps best marked by the paper by C. J. Pedersen published in 1967, describing the synthesis of a number of crown ethers, and most importantly, the ability of these macrocycles to form stable complexes with simple inorganic cations.<sup>46</sup> The development of the macropolycyclic cryptands, by J. M. Lehn, followed soon after.<sup>47</sup> The pioneering work of C. D. Gutsche in the mid-1970s initiated study of the macrocycles now known as calixarenes.<sup>48</sup> The rapid expansion of this field forces us to limit the discussion here to some representative aspects of metal complexes of these O-donor macrocycles.

## 7.2 Crown Ethers and Cryptands

### 7.2.1 Complexation

The crown ethers form stable complexes with many cations, both inorganic and organic, as well as neutral species.<sup>49</sup> As would be expected, the Macrocyclic Effect (see *Macrocyclic*) provides a significant contribution to this stability. For example, the stability constant of the  $K^+$  complex of 18-crown-6 in anhydrous methanol is  $10^{6.1}$ , whereas the complex of the open chain analog has a stability constant of  $10^{2.3}$ . The tricyclic cryptands are even more preorganized, and generally form more stable complexes than the corresponding crown

ethers (this is sometimes called the ‘cryptate effect’).<sup>49</sup> The preorganization concept is taken to its logical conclusion in the class of receptors termed *spherands*, which are fully preorganized for the target guest producing extremely stable complexes.<sup>50</sup>

The crown ethers and cryptands generally form more stable complexes with ‘hard’ metal ions, such as the group 1, 2, and lanthanide ions. The introduction of softer heteroatoms into the macrocycle can change the selectivity dramatically. There is much interest in ‘tuning’ macrocycles in this way to favor complexation of certain metal atoms, but O-donor macrocycles will dominate the discussion here.

There has been a great deal of work on group 1 metal ion complexes of crown ethers and cryptands, producing many estimates of stability constants and other thermodynamic data. The importance of factors such as relative sizes of the cation and the macrocycle cavity has been widely discussed (the ‘hole-size’ effect). This concept is of most use in relatively rigid systems such as the cryptands, where the receptor molecule cannot easily distort to accommodate cations of the ‘wrong’ size. Thus, [2.2.2]cryptand has a cavity size close to the ionic radius of  $K^+$ , and it complexes this cation selectively over the smaller  $Na^+$  and larger  $Cs^+$ . In more flexible systems, other factors such as ligand conformations, chelate ring size and solvation enthalpy become relatively more important, so that a simple match of cation and macrocycle hole size is generally not sufficient to predict selectivity.<sup>51</sup> Changing solvents, for example, can reverse the trends in stability constants in some systems. The thermodynamics and kinetics of cation/macrocycle interaction is an important area of study, and a great deal of the available data has been compiled by R. Izatt and coworkers, along with useful discussion of the factors influencing the stability of the complexes.<sup>52,53</sup>

### 7.2.2 Structural Aspects

The solid-state structures of crown ether complexes can be broadly categorized on the basis of relative sizes of the cation radius and the macrocycle cavity. The simplest case is where there is a close fit between the cation and macrocycle; a beautiful example of this is the potassium complex of 18-crown-6 (**86**). The  $K^+$  ion is bound to all six O atoms of the crown, and sits in the plane of the macrocycle. The structural chemistry of this seemingly complementary pairing is far from simple, however, and a range of different structural types has been found for these complexes.<sup>51</sup> For example, additional ligands are often found coordinated to the potassium cation in 18-crown-6 complexes, as shown for (**87**) where two thf molecules are bound to the potassium cation, above and below the plane of the macrocycle. Remarkably, structures (**86**) and (**87**) are found in a single crystal structure,<sup>54</sup> illustrating that subtle changes can induce different crown ether complex structures.

If the cation is large relative to the cavity size of the macrocycle, the cation can still interact with the crown ether,

(86)  $[K^+(18\text{-crown-6})]^{54}$

(87)  $[K^+(18\text{-crown-6})(\text{thf})_2]^{54}$

by ‘perching’ out of the average plane of the crown. There are a number of structural types that can occur in such complexes. One case is the formation of a complex with the metal ion situated above the crown, and the coordination sphere saturated by other ligands; an example of this is the  $[Sm(15\text{-crown-5})(H_2O)_4]^{3+}$  cation (**88**).<sup>55</sup> Alternatively, a 1:2 complex may be formed, with the metal ion sandwiched between two crown ethers. The  $K^+$  complex of 15-crown-5 (**89**) exhibits such a structure, with the ten-coordinate  $K^+$  ion bound to all the O-donor atoms of the two crowns.<sup>56</sup> A sandwich-type structure is also possible in 1:1 crown ether complexes, as shown for the  $CsSCN$  complex of 18-crown-6 (**90**).<sup>57</sup> In this case, the  $SCN^-$  ligands act as bridges to give the  $Cs^+$  ion a coordination number of eight. A triple layer ‘club sandwich’ structure with a 2:3 metal to crown ratio has also been observed in a  $Cs^+$  complex of 18-crown-6.<sup>58</sup>

Examples where the metal cation is small compared to the size of the macrocycle fall into two categories. The most common result is a constriction of the crown ether cavity, so that the macrocycle shrinks to match the cation radius. An example is the  $Na^+$  complex of 18-crown-6 (**91**);<sup>59</sup> the conformation of the crown is quite distorted compared to that observed in (**86**), with five of the O-donor atoms lying in a plane about the metal ion, and the sixth folded out of the plane.

(88)

(91)

resemblance to the complexes formed by natural ionophores such as valinomycin.

(89)

(90)

(92)

Distortion such as this may result in the exclusion of one or more of the crown O atoms from the coordination sphere of the metal. This situation is found in another  $\text{Na}^+$  complex of 18-crown-6 (**92**), again showing that subtle structural differences can occur for the same cation-crown combination.<sup>60</sup> Extremely large and flexible crown ethers can completely encapsulate metal ions, as is found in the  $\text{K}^+$  complex of a 30-crown-10 ligand, and the  $\text{Na}^+$  complex of a 24-crown-8 derivative, for example.<sup>51</sup> This ‘wrapping’ of the cation bears structural

The second structural type that can be formed where the cation is small relative to the macrocycle is a bimetallic complex where the crown contains two metal ions. One example is the disodium complex of dibenzo[24]crown-8 (**93**), where each sodium ion is bound to three O atoms of the crown.<sup>61</sup> Such complexes are relatively rare, and usually limited to singly charged cations, presumably for electrostatic reasons.

The complexes discussed so far all involve direct interaction between the metal ion and the crown ether. Another important class of crown ether derivatives is that involving second sphere coordination.<sup>62</sup> These compounds involve interaction between the ligands in the primary coordination sphere (such as  $\text{H}_2\text{O}$  in  $\text{M}(\text{H}_2\text{O})_6^{n+}$  cations), and the second sphere ligand, the crown ether, often by means of hydrogen bonds. Such a structure is found in the  $[\text{Mn}(\text{OH}_2)_6](\text{ClO}_4)_2$  adduct of 18-crown-6 (**94**).<sup>63</sup> It is not surprising that transition metal/crown ether chemistry often involves adducts, since

$[\text{Na}_2(\text{benzo-24-crown-8})(2\text{-nitrophenolato})_2]$  – only O-atoms of bridging phenolates shown for clarity<sup>61</sup>

ligands such as  $\text{H}_2\text{O}$  and  $\text{NH}_3$  tend to bond to transition metal ions more strongly than the crown ethers. Aqua and ammine complexes dominate this area, although interaction between acidic methyl group C–H bonds and crown ethers has been observed. It is interesting to note the formation of complexes where the crown ether is simultaneously involved in both the primary and secondary coordination spheres. This is often observed where the cation is small relative to the crown ether. An example is the lithium complex of 18-crown-6 (95), where water molecules coordinated to the lithium cation also form hydrogen bonds with the crown ether O atoms.<sup>64</sup>

$[\text{Li}(\text{18-crown-6})(\text{OH}_2)_2]^+$ <sup>64</sup>

three-dimensional cavity, as shown for the  $\text{K}^+$  complex of [2.2.2]-cryptate (96). The cavity can expand to accommodate larger cations, and this is often accompanied by coordination of solvent or anionic ligands; for example, the  $[\text{Eu}(\text{ClO}_4)([\text{2.2.2}]\text{-cryptand})]^{2+}$  cation is 10 coordinate with bidentate coordination of the  $\text{ClO}_4^-$  anion.<sup>65</sup> As mentioned above, the cryptands are less flexible than the crown ether, and this is reflected in the less variable structures of the metal complexes.

$\text{Mn}(\text{H}_2\text{O})_6^{2+} \cdot 2(\text{18-crown-6})$ <sup>63</sup>

Crystal structure determinations of various cryptates have shown that the metal atom is usually held within the

## 7.3 Calixarenes

### 7.3.1 Introduction

An interesting group of aryloxides are the macrocyclic polyphenols known as calix[*n*]arenes (97), where *n* indicates the number of aryl units comprising the macrocycle.<sup>48,66</sup> More recently, the term calixarene has been extended to include macrocycles comprising of other aromatic units (such as resorcinols, naphthols, pyrroles, furan, etc.);<sup>66</sup> here, the discussion will be limited to the calixarenes produced from the base catalyzed condensation of para-substituted phenols and formaldehyde. The most common ring sizes are *n* = 4, 6, or 8, although ring sizes up to *n* = 20 have been isolated.<sup>66</sup> The phenolic calixarenes act as effective ligands, particularly for hard metal cations. The parent macrocycles can also be functionalized in a wide variety of ways to give macrocycles with desired properties. A brief overview of the phenolic calixarenes, and then derivatized calixarenes, as ligands is given below.

### 7.3.2 Phenoxide Calixarene Complexes

The cyclic tetramer is the smallest readily available calixarene; it can assume a number of conformations, but is most commonly found in the conelike conformation (98)

that gave rise to the name calixarene (from the Greek *calix* meaning 'vase'). Metal cations typically interact with the phenol O-donor atoms at the lower rim of the calixarene forming mono or binuclear complexes;<sup>48</sup> the 2:2 europium complex of *p-t*-butylcalix[4]arene (**99**) is a typical example.<sup>67</sup> Conversely, the cation  $\text{Cs}^+$  has been shown to occupy the cavity defined by the aromatic rings (**100**).<sup>68</sup>

Cesium complex of *p-t*-butylcalix[4]arene<sup>67</sup>

Cone conformer of calix[4]arene

Europium complex of *p-t*-butylcalix[4]arene  
[Eu<sub>2</sub>(dmf)<sub>4</sub>(*t*-butylcalix[4]arene-3H)<sub>2</sub>] (butyl groups omitted for clarity)<sup>66</sup>

The quasi-planar array of oxygen atoms at the lower rim of the calix[4]arene has inspired studies of calix[4]arene-metal complexes as models for metal-oxo surfaces of heterogeneous catalysts.<sup>69</sup>

Structurally characterized complexes of larger calixarenes are less common than those of calix[4]arenes, but the number

is rapidly increasing.<sup>70</sup> Calix[6]arenes have been found to act as a ditopic ligand for a number of alkali metals and transition elements, although a Eu<sup>III</sup> complex of *p-t*-butylcalix[6]arene was found to have a 1:2 metal:calixarene ratio, where one calixarene was bound to the metal atom by only one phenolic O atom, and the other was free in the crystal lattice.<sup>71</sup>

Calix[8]arenes are also found to act as a ditopic receptor in most cases.<sup>66,70</sup> The calixarenes assume various 'pinched' conformations in these complexes, resembling two calix[4]arene cone units linked together. Two 1:1 complexes, of Ca<sup>II</sup> and Eu<sup>III</sup>, have been characterized where a roughly planar circular conformation is observed, with only two of the phenolic O atoms interacting with the metal atom.<sup>70</sup> It is interesting to note that the free *p-t*-butylcalix[8]arene has been found to crystallize as a pyridine solvate with a planar, circular conformation in one case, and a pinched conformation in a subsequent report.<sup>48</sup>

### 7.3.3 Derivatized Calixarene Complexes

Both the lower (phenolic) rim and the upper rim of the calixarene can be functionalized. A huge range of calixarene derivatives have been synthesized in this way, and only a few can be mentioned here. In addition, the linking methylene groups can be modified to give another group of useful ligands.<sup>48</sup>

Alkylation of the lower rim substitution with carbonyl-containing groups (**101**) has produced probably the most widely studied of the calixarene-based ionophores.<sup>72</sup> These derivatives have been studied predominantly as ionophores for hard metal cations, and can form complexes of comparable stability to those of the cryptands in some cases. Such calixarenes have found applications as ionophores in ion selective electrodes.<sup>73</sup>

Lower rim substitution can also be used to link calixarene molecules. An elegant example was produced by linking two calix[4]arenes with four ethylene bridges to produce what was termed as a calix[4]tube (**102**).<sup>74</sup> The synthesis was templated by the potassium ion, and the product was found to bind this cation selectively.

“Calix[4]tube” potassium complex<sup>73</sup>

Upper rim substitution is typically more synthetically challenging than the lower rim, but can confer very useful properties on the macrocycle. For example, water soluble *p*-sulfonatocalixarenes have been synthesized and found to be highly water soluble, unlike the hydrophobic *p*-*t*-butyl derivatives.<sup>75</sup> The sulfonated calixarenes form a variety of metal complexes where the metal is usually bound to the sulfonato groups of the calixarene.

Finally, both upper and lower rim substitution have been used to produce a class of macrocycles referred to as *calixarene-crown ethers*, or *calixcrowns*. One simple example is shown here (103). These receptors combine characteristics of the crown ethers and calixarenes, and have been intensively studied for metal ion extraction, in particular, for the removal of cesium from nuclear waste.<sup>76</sup>

## 8 MISCELLANEOUS $\eta^1$ O-DONOR LIGANDS<sup>77</sup>

### 8.1 Dialkyl Sulfoxides

The most widely studied is dimethyl sulfoxide (DMSO), with the number of studies increasing sharply in the mid-1960s, when DMSO became commercially available. DMSO

can form O-bonded and S-bonded complexes, with hard metal ions generally forming O-bonded complexes and softer metal ions S-bonded complexes as expected.<sup>78</sup> Complexes such as  $[\text{RhCl}_3(\text{OSMe}_2)(\text{SMe}_2\text{O})_2]$ , containing both O- and S-bonded DMSO, have been described, however.

DMSO complexes can often be prepared simply by dissolving the appropriate metal salt in DMSO, and then precipitating the complex by adding a less polar solvent such as benzene. The hydrated metal salt can often be used in this process, although in the preparation of other dialkyl sulfoxide solvates it has been found that removal of water is necessary.

### 8.2 Carboxylic Acid Amides

The carboxylic acid amides most commonly studied as ligands are formamide, acetamide, and the *N*-substituted derivatives, particularly *N,N*-dimethylformamide (DMF). These compounds are often used as solvents and have high dielectric constants, particularly when they contain an N–H bond, and such uses helped to stimulate interest in the amides as ligands. There are two possible donor atoms, N or O, but all complexes of the simple amide ligands, characterized by X-ray structure determination at least, have M–O bonds. The amides are usually terminal ligands but can bridge between metal atoms in some instances.

The carbonate acid amides are not generally as strongly bound as the dialkyl sulfoxides and water competes for coordination sites, giving products containing coordinated amide and water. Anhydrous reagents, or dehydration procedures using triethyl orthoformate or 2,2'-dimethoxypropane, are generally required in the preparation of such complexes. In addition, complexes containing the amide and an anionic ligand are often obtained when the anion has some coordinating ability (e.g.  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ), to give molecular rather than ionic species.

### 8.3 Amine *N*-oxides

The majority of studies involve aromatic N–O ligands, some common examples being pyridine *N*-oxide and methyl substituted derivatives (104–106). They are versatile ligands,

forming complexes with almost every element. The *N*-oxide ligands can often be displaced by water, and hence the complexes are generally prepared under anhydrous conditions.

(104) pyNO

(105) 2-MepyNO

(106) 2,6-diMepyNO

The first-row transition metals generally form octahedral complexes  $[M(\text{pyNO})_6]^{n+}$  with pyridine *N*-oxide in the absence of other competing coordinating agents. An interesting example is  $[\text{Cu}(\text{pyNO})_6](\text{ClO}_4)_2$ , which has a regular octahedron of O atoms about the Cu atoms, rather than the expected Jahn–Teller distortion. Ligands with substituents ortho to the nitrogen atom can tend to form complexes with lower coordination numbers, such as four-coordinate  $\text{Co}^{\text{II}}$  in  $[\text{Co}(2,6\text{-diMepyNO})_4](\text{ClO}_4)_2$ .

#### 8.4 Phosphine Oxides and Arsine Oxides

These ligands have the general formulae  $\text{OPX}_3$  where X = alkyl or aryl (R), OR,  $\text{NR}_2$  or halide, and  $\text{OAsR}_3$ . The most widely studied of these is  $\text{OPPh}_3$ . Complexes are prepared by direct reactions of the ligand and a metal salt in an organic solvent. The ligands form M–O bonds, and can form bridges between metal atoms. In almost all cases, no more than four of the bulky triphenylphosphine oxide ligands are found coordinated to a metal center, with the remainder of the coordination sphere comprising of smaller ligands.

IR spectroscopy has been useful in detecting interactions between these ligands and metal ions, by virtue of the lowering of the P–O and As–O stretching frequencies upon complexation.  $^{31}\text{P}$  NMR has also been investigated but is of limited use, since most systems exhibit fast ligand exchange on the NMR timescale.

## Glossary

*Atlas*: ch. Baerlocher, W. M. Meier and D. H. Olson, 'Atlas of Zeolite Structure Types', Elsevier, 2001

*Basalt*: fine-grained rock of volcanic origin

*Biogenic*: produced from living organisms

*Borolanite*: coarse-grained volcanic rock with high feldspar and feldspathoid content

*Boronation*: reaction of borane ( $\text{BH}_3$ ) with OH groups

*Carboniogenic*: production of carbon cations from hydrocarbons

*Clathrate*: a three-dimensional assemblage of molecular units, held together by weak van der Waals type forces, forming cavities of molecular dimensions in which can be located 'guest' molecules

*Cracking*: splitting of the long hydrocarbon chains in crude oil to small molecular units

*Crown ether*: complex synthetic organic molecule containing ether 'rings'

*Crystal system*: classification of crystals by the symmetry of their external or internal geometries

*Cubic close packing*: arrangement of atoms in a crystal in their closest possible way having cubic symmetry

*Diagenesis*: process that affects a sediment while it is at, or near, the Earth's surface (caused by temperature and pressure)

*Dyke*: a vertical sheet of igneous rock extruded into an existing rock

*Fault plane*: layers in a crystal structure at which defect(s) arrangements in the normal stacking of the layer can occur

*Feldspar*: alkali aluminosilicate rocks with dense framework structures

*Feldspathic*: containing feldspar minerals

*Feldspathoid*: natural aluminosilicate minerals with framework structures containing water and salt molecules in their cavities

*Gas-solid chromatography*: analytical separation of gases on a solid, porous, substrate

*Granodiorite*: coarse-grained acid rock of volcanic origin

*Guest*: molecule trapped inside a clathrate

*Hexagonal close packing*: as for cubic close packing but with adoption of hexagonal symmetry

*Hydrolysis*: splitting of water molecules to give  $\text{H}^+$  and  $\text{OH}^-$  species

*Ignimbrite*: tuffs welded by their high-temperature deposition caused by the emission of an incandescent cloud of gas and ash from a volcano (a 'nuée ardente')

*Intergrowth*: simultaneous crystallization of two minerals

*Intumescence*: visible loss of water with heating

*Isotypic*: having the same structure

*Magma*: molten fluid formed within the Earth's crust or mantle containing molten silicates, water, and gases; magma that is extruded on to the surface of the Earth is called lava

*Metamorphism*: change created in rocks by heat, pressure, and chemically active fluids within the Earth's crust

*Meteoric (water)*: water that percolates rocks from above (e.g. from rivers, rain, snow, etc.)

*Microporous*: solid material containing pores of less than about 20 Å in diameter

*Molecular sieve*: a structure that can separate molecules on the basis of size

*Mepheline*: a sodium feldspathoid

*Pegmatite*: coarse-grained mineral vein with well formed crystals

*Plagioclase*: sodium/calcium aluminosilicate mineral of the feldspar group

*Pyroclastic*: ejected by volcanic eruption

*Radiolarians*: a protozoon having a silica skeleton

*Sedimentary*: processes whereby rocks (minerals) are formed from materials derived from other rocks by weathering, erosion, and transportation

*Silanation*: reaction of silane ( $\text{SiH}_4$ ) with OH groups

*Sorption*: uptake of liquid or gas by a microporous material

*Space-filling*: spatial arrangement of polyhedra such that each polyhedron shares all its faces with other polyhedra

*Stacking fault*: misalignment of layer(s) arising from a fault plane

*Stoichiometry*: the relative numbers of atomic constituents making up a chemical compound

*Truncated octahedron*: a polyhedron composed of eight hexagonal and six square faces

*Tuff*: ash and dust blown out of a volcano during eruption and subsequently consolidated

*Unit cell*: the smallest repeating structural unit in a solid structure at the atomic scale

*Zeolites*: natural and synthetic hydrated aluminosilicates with open framework structures enclosing cavities and channels in which reside mobile cations and water molecules

*Zeotypes*: zeolite-like framework structures with atoms other than Si, Al in the tetrahedral positions in the framework

## Abbreviations

AlPO<sub>4</sub> = Aluminophosphate; BP = British Petroleum; BET = Brunauer, Emmett, and Teller; DABCO = 1,4-diazabicyclo[2,2,2]octane; FCAPO = Framework constituent aluminophosphate; FCC = Fluidized bed cracking catalyst; LPG = Liquid petroleum gas; MAS NMR = Magic angle spinning nuclear magnetic resonance; MeAPO = Metal aluminophosphate; MeAPSO = Metal silicoaluminophosphate; PSA = Pressure swing application; REY = Rare earth exchanged synthetic zeolite Y; SAPO = Silicoaluminophosphate; SBU = Secondary building unit; T = tetrahedrally coordinated atom; TEA = Triethanolamine; TMA = Tetramethylammonium; TPA = Tetrapropylammonium; UOP = Union Oil Products, USA; USY = Ultrastable synthetic zeolite Y; VEB = VEB Leuna Werke, Bitterfeld, Germany; XAPO = Aluminophosphate containing Fe, Ti, as T atoms; ZSM = Zeolite Socony Mobil.

## 1 INTRODUCTION

In 1756, Cronstedt,<sup>1</sup> a Swedish mineralogist, discovered a new mineral that visibly lost water when heated. Because of this easily observed intumescence, he coined the word 'zeolite' from two Greek words 'zein' and 'lithos', meaning 'boiling stone', to name the new species. Cronstedt's mineral was later named stilbite.

This facile loss of water was shown to be reversible by Damour<sup>2</sup> (1840) and, in 1858, Eichorn<sup>3</sup> showed that the zeolite chabazite contained alkali and alkaline earth metals, which were capable of being reversibly replaced, that is, the zeolite exhibited cation-exchange properties. Analysis of zeolite minerals showed them to be aluminosilicates and their easy loss of water and cation exchange was evidence for the open nature of their structures, often likened to a sponge. The description 'zeolitic water' has been widely used to describe loosely held water in any solid.

The need for commercial water softeners prompted attempts to synthesize zeolites. These were not successful, although St Claire Deville<sup>4</sup> (1862) claimed to be able to make levyne. The early attempts at zeolite synthesis have been extensively reviewed by Morely and Ingersoll<sup>5</sup> (1937). Lack of available, definitive, characterization methods makes it difficult to confirm their work.

Progress to 1925 was largely through mineralogical identification of new zeolite species but in this year Weigel and Steinhoff<sup>6</sup> reported that chabazite sorbed water, methanol and

ethanol, and methanoic (formic) acid but excluded acetone, ether, and benzene. The significance of this observation was realized by McBain,<sup>7</sup> who described it as a 'molecular sieving' effect (1932). In 1930, Taylor<sup>8</sup> solved the structure of analcime and Pauling<sup>9</sup> published a series of seminal papers based upon single-crystal X-ray studies, which showed how silicates and aluminosilicates were constructed from tetrahedral building blocks, that is, the [SiO<sub>4</sub>]<sup>4-</sup> and [AlO<sub>4</sub>]<sup>5-</sup> units of structure. His work included the zeolite natrolite and the feldspathoids sodalite and cancrinite, which are now known to have structures closely related to the zeolite minerals. Figure 1 shows the Si/Al coordination tetrahedra and their linking to create the chain-like element of structure identified in natrolite. The importance of Pauling's work was that it illustrated the way in which the tetrahedral units linked by sharing all corners to produce the three-dimensional framework structures associated with the zeolite and feldspathoid minerals. It is this regular and reproducible molecular architecture that confers on the zeolites their uniquely useful properties.

This was evident to R. M. Barrer<sup>10</sup> who from the mid-1930s to 1996 provided the scientific base upon which the current widespread industrial use of zeolites has been founded. His pioneering work on zeolite synthesis, ion exchange, gas sorption, and structures, from both theoretical and practical standpoints, has spawned the continuing growth of zeolite science and technology encouraged by the discovery of their catalytic properties in the early 1960s. The world's zeolite literature continues to grow at a rate of close to 100 publications per week. This is almost entirely devoted to synthetic materials of zeolite structure type, and has caused a reassessment of the strict mineralogical concept of zeolites as aluminosilicates containing mobile cations and water molecules that promote the properties of cation exchange and reversible water uptake.

This will be considered in detail later in this article but it is convenient first to consider the assemblages of (Si,Al)

**Figure 1** Si,AlO<sub>4</sub> tetrahedra linked as in the zeolite natrolite

tetrahedra, which can be recognized as forming part of zeolitic frameworks.

## 2 ZEOLITE STRUCTURES

### 2.1 Introduction to Zeolite Structures

The picture of a zeolite structure can now be refined as closer to a honeycomb of channels and cavities created by rigidly (at room temperature) linked tetrahedra. The three-dimensional structures are constructed from pores of molecular dimensions, that is, zeolites are microporous solids. The *Atlas of Zeolite Structure Types* 5th Edition edited by Baerlocher, Meier, and Olson,<sup>11</sup> defines the framework density in terms of the number of tetrahedrally coordinated atoms ( $T$ ) per unit of  $1000 \text{ \AA}^3$ , and sets 20–21  $T$  per  $1000 \text{ \AA}^3$  as the lower limit of micro-porosity. The current upper limit is about 11  $T$  per  $1000 \text{ \AA}^3$  in a synthetic framework structure known as cloverite. The *Atlas* will be used as a major source throughout this section. The *Atlas* lists all known zeolite-type frameworks and encompasses materials not previously included in the restricted definition of zeolites as being only continuous aluminosilicate structures. This extension will be expanded on later but it is important to appreciate that the major bases for definition are the recognition of micro-porosity, as mentioned above, and the identification of structural subunits constraining the pores and cavities within the frameworks. These are called secondary building units (SBUs) and can be simple arrangements of tetrahedra to construct obvious arrangements such as four-, six-, or eight-membered rings or more complex structures (Figure 2). They contain up to 16 tetrahedral ( $T$ ) atoms and are identified as being the only SBU linking to produce an entire and unique zeolite framework. The more simple SBUs are often described as oxygen rings or windows (clearly linkage of, say, six tetrahedra by two of their corners to create an hexagonal ring will also produce a ring of six oxygens).

Table 1 lists their shorthand notation often found in zeolite texts.

**Table 1** Simple zeolite SBUs and their shorthand notation

| Number of linked tetrahedra | SBU created      | Shorthand description <sup>a</sup> |
|-----------------------------|------------------|------------------------------------|
| 4                           | 4 oxygen ring    | S4R                                |
| 5                           | 5 oxygen ring    | S5R                                |
| 6                           | 6 oxygen ring    | S6R                                |
| 8                           | 8 oxygen ring    | S8R                                |
| 8                           | 4–4 oxygen rings | D4R                                |
| 12                          | 6–6 oxygen rings | D6R                                |
| 16                          | 8–8 oxygen rings | D8R                                |

<sup>a</sup>S = single, D = double.

**Figure 2** Secondary building units (SBUs) of zeolite structures. (Reproduced by permission of Butterworth-Heinemann from Baerlocher, Meier, and Olson<sup>11</sup>)

### 2.2 Oxygen Windows

In some zeolite-type structures, the spatial linkages between these SBUs produce oxygen windows that define the useful pore diameters within the zeolite structures. These provide another way of classifying zeolite frameworks but it must be realized that these oxygen windows arise from the geometric arrangements of SBUs and are not necessarily the SBUs themselves.

Tables 2–5<sup>11</sup> lists all known zeolite-type frameworks on the basis of their major pore dimensions, and Table 6 illustrates the shorthand notation used. The pore diameter dimensions are based upon crystallographic measurements assuming that the oxygen radius is  $1.35 \text{ \AA}$ . Note that not all pores are circular, or planar, so maximum and minimum diameters are given in these cases and even these may be

**Table 2** Zeolite frameworks by channel geometries of largest pores in structures containing 14, 18, and 20-membered oxygen rings<sup>11</sup>

| IUPAC code | Name                 | Ring | Channel geometries and ring size ( $\text{\AA}$ )                                          |

altered by the state of hydration of the framework and also are temperature dependent. The maximum flexibility of the oxygen windows is roughly 0.3 Å over their useful temperature range. Included in Tables 2–5 are the structure-type codes allocated by the IZA Structure Commission following the rules set up by an International Union of Pure and Applied Chemistry (IUPAC) Commission on Zeolite Nomenclature. These tables include:

1. natural aluminosilicate zeolites;
2. natural minerals with zeolite frameworks but with tetrahedrally coordinated atom (T) atoms *other* than Si or Al (zeotypes).
3. structures basically of zeolite framework type but not strictly three-dimensional in that a proportion of the subunits are not linked by all tetrahedral corners; in these cases, terminal OH groups are included in the incomplete ‘frameworks’ and this is signified by a hyphen that precedes the IUPAC code, as in ‘–PAR’ for partheite;
4. synthetic aluminosilicate zeolites;
5. synthetic zeotypes;
6. synthetic and natural phases of silica constructed from SBUs;
7. feldspathoids, for example, cancrinite; this arises because the cancrinite cage structure can be identified as a structural subunit of zeolites, that is, as a zeolitic cavity, and the *Atlas* includes several feldspathoid frameworks because of their close relationship to zeolites;

These subheadings will be used later to furnish a more detailed description of zeolite structure types.

## 2.3 Zeolite Channels

Each channel system is defined as being one-, two-, or three-dimensional with respect to the zeolite framework and a simple notation describes whether or not the channel

**Table 4** Listing of zeolite frameworks containing 10 and nine-membered rings (10SR, 9SR) in their main channels<sup>11</sup>

| IUPAC code | Name                  | Channel geometries                                            |

systems interconnect and their spatial relationships to the crystallographic axes of the zeolite unit cell (see Table 6).

Three examples will suffice to demonstrate this information: Figure 3 shows the polyhedral units in the synthetic zeolite Linde Type A, which link to provide a three-dimensional interconnecting array of channels, Figure 4 illustrates the essentially two-dimensional system of channels in the mordenite framework, and Figure 5 shows the major channels in synthetic zeolite Linde Type L arranged as parallel one-dimensional channels and shown as a stereo pair. Table 6 lists the *Atlas* notations for these structures with explanations, including the symbols used in Tables 2–5.

## 2.4 Zeolite Structural Families

As has been discussed already, the primary building unit of all zeolite and zeotype frameworks is the tetrahedral unit, which can be linked to produce the SBUs seen in Figure 2. In some cases, it is convenient to describe zeolite structure-type frameworks by the recognition of larger assemblages of tetrahedra. Examples of this approach will now be discussed to emphasize how it can be used to simplify complex frameworks.

### 2.4.1 Structures Based upon Linkages of the Double Hexagonal Ring SBU, (D6R)

The chabazite framework is a sequence of D6R units joined, via S4Rs, into the same sequence as that in cubic close packing, that is, ABCABCABC (see Figure 6, also Figure 2 and Table 1). This means that an easy way to describe the chabazite structure is that of a NaCl-type arrangement with a D6R unit at each corner of a simple cubic assemblage.

This produces a large cavity, created by the D6R constructional elements, and access to it is governed by passage through an eight-oxygen aperture (S8R) as listed in Table 5. Eleven specific cation and water locations have been identified by single-crystal X-ray studies within the chabazite framework. In the natural mineral, some calcium ions reside in the D6Rs in the dehydrated state, but in the fully hydrated mineral, the cations have near complete coordination spheres of water and ‘float’ inside the larger cavities.

The movement from relatively loosely bound sites within the larger cavities to smaller cages with little associated water is common behaviour for cations in zeolites. Their presence in the large cavities, in what has been described as a brine is, of course, the source of facile cation-exchange properties. It

has been estimated that the hydrated cation concentration in zeolite cavities is around 5 M.

Gmelinite also has a framework, which can be described as a linkage of D6R units. In this case, they are arranged in the sequence ABABAB, that is, that of a hexagonal close-packed array. This architecture also produces a large cavity containing sites for four divalent hydrated cations.

An extension of this approach can be to consider stackings of S6R SBUs in the zeolite structure so that chabazite would be described as AABBCAABBCC and gmelinite

as AABBAABB. On this basis, erionite has the stacking arrangement of AABAAC and offretite AABAAB (Figure 7). These zeolites often occur naturally as intergrowths, and from the same syntheses, as might be anticipated from their framework similarities.

#### 2.4.2 Structures Based upon Linkages Between Chains of Tetrahedra

In phillipsite, S4R are linked to form chains resembling a double crankshaft (Figure 8). Gismondine has a related

<sup>a</sup>Number of asterisks denotes dimensionality of the channel. Other symbols used in Tables 2–5: | no direct access from one channel system to another;  $\perp$  channels interconnect at right angles; + two constrictions to the same channel.

**Figure 3** Framework of synthetic zeolite A (LTA) showing constituent cage structures and their dimensions**Figure 4** Framework of mordenite (MOR) showing channels

structure but with chains joined together in a different way, as shown in Figure 9. The differences can be seen to be variations in the relative spatial orientations of the linked tetrahedra described as up (U) and down (D), and adjacent tetrahedra are arranged as two pointing up and two down (UUDD). Note that, again, restricting S8R units have been created (Table 5), but of different diameters to those seen in chabazite. The cations reside close to the S8R positions.

It must be emphasized that both phillipsite and gismondine have unique frameworks. Mineralogically speaking they both are members of different families (see Tables 11 and 13).

Figure 1 illustrated the chain of tetrahedra identified in the natrolite framework. These are of UDUD alignments derived

from the 4–1 SBU (Figure 2) whereby the ‘1’ links adjacent chains. Other zeolites in this family are mesolite, gonnardite, and scolecite (see Table 12). The natrolite family of structures also has S8Rs as restricting dimensions. The cations sit in sites close to four oxygens, two each from adjacent 4–1 chains. They are relatively unhydrated at these sites and are difficult to replace by ion exchange.

#### 2.4.3 Structures Based upon Assemblages of Cages

In some cases, it is easiest to describe a zeolite by relating the framework to a series of component polyhedra, each polyhedral cage being a clustering of linked tetrahedra. The

**Figure 5** Stereopair of zeolite L (LTL) structure viewed along [001]

**Figure 6** Structure of chabazite showing AABBC sequence of S6Rs

best-known example of this approach is for the synthetic zeolites A, X, and Y.

The polyhedra making up the A framework can be seen in Figure 10. The smallest unit is the D4R SBU, which joins truncated octahedral units to surround a large central cavity. The truncated octahedra are the structural unit of the feldspathoid sodalite (discussed later). These sodalite cages are also often described as  $\beta$ -cages while the large cavity, which has 48 sides, is known as an  $\alpha$ -cage or a 'Type I' 26-hedron. Note that the LTA framework is composed entirely of these three polyhedra, which share all their faces with each other. This is therefore a space-filling structure. An alternative view of the LTA-type structure is as a series of  $\beta$ -cages jointed by cubes (D4R) to propagate cubic symmetry in which each  $\beta$ -cage occupies a position analogous to that of the atoms in an NaCl array, that is, a similar approach to that described in chabazite.

(a)

(b)

**Figure 9** Linkage of chains in (a) phillipsite (PHI) and (b) gismondine (GIS)

This way of imagining polyhedral linkages can be extended to consider the FAU framework shared by the synthetic

**Figure 10** LTA structure emphasizing the linkage of truncated octahedra ( $\beta$ -cages) via D4R units (compare with Figure 3)

**Figure 11** Faujasite (FAU) structure emphasizing the linkage of truncated octahedra ( $\beta$ -cages) via D6R units

zeolites X and Y and the natural zeolite faujasite. Here (Figure 11) the composite polyhedra are the 6DR, which

link  $\beta$ -cages to create a large internal cavity, the 'Type II' 26-hedron. Again this is a space-filling arrangement that can be alternatively viewed as an assemblage of  $\beta$ -cages joined by one half of their available S6R faces to produce another framework of cubic symmetry in which the sodalite units have the same spatial arrangement to each other, as do the carbon atoms in a diamond lattice. Zeolite X and Y are synthetic faujasites with the FAU framework, and differ only in the relative amounts of Si and Al isomorphously substituted in tetrahedral interstices. Their cation sites will be considered later.

#### 2.4.4 Summary

This section has attempted to give an appreciation of the ways in which zeolite structures arise. It has not been intended to be all-encompassing and other types of framework will arise in further sections. It will also be appropriate to introduce additional information on zeolite cation and water locations on various industrially significant zeolites. Not all zeolites will be described and full details of known cation and water sites were collated by Mortier to 1982.<sup>12</sup> No further compilation has yet been made.

### 3 ZEOLITE COMPOSITIONS

#### 3.1 Natural Aluminosilicate Zeolites

Table 7 lists the currently known aluminosilicate zeolites based upon definition by their unique frameworks following Baerlocher, Baerlocher, Meier, and Olson.<sup>11</sup> It also contains typical unit cell compositions, the IUPAC code, and type localities, but is restrictive in the sense that it does not consider the mineralogical aspects of the study of zeolites. The authoritative body for these is the Subcommittee for Zeolite Nomenclature of the Commission on New Minerals and Mineral Names of the International Mineralogical Association. Their guidelines have been cited in a recent book on natural zeolites by Tschernich,<sup>13</sup> as follows.

1. A new zeolite must have a unique framework. Evidence of a framework different from existing species must be demonstrated as a condition for approval of a new species. Zeolites that have the same framework and are separated by a well-established gap in chemical composition that is controlled by the structure are acceptable as separate species.
2. A new mineral cannot be defined solely on the basis of exchangeable cations. Because cations in zeolites are largely exchangeable, the dominance of one over all the others should not be the basis for a mineral species. End members, or intermediate members, of a zeolite composition cannot be considered new species. Existing

species with the same frameworks that are defined only by the exchangeable cations should be redefined.

3. A new zeolite cannot be defined solely on the basis of Si/Al ratio.
4. A new zeolite cannot be defined solely by the symmetry difference from order or disorder of the aluminum and silicon in the framework.

Following these guidelines extends the list of accepted naturally occurring zeolite species because, as seen in Section 2.4.2, there are families of zeolites with the same framework but of different cation content. In some cases, the guidelines have become blurred with inconsistencies arising whereby end members of cation composition are accepted as distinct zeolite species in one family but not in another.

Before going on to list these families, one further point needs to be made. This arises because there are several instances where a unique zeolite framework has been first characterized from a laboratory preparation and later identified as a natural species. The first of these was mazzite, prepared first as synthetic zeolite ZSM-4 (or omega) but known in nature prior to the allocation of the IUPAC code; hence its inclusion in Table 7. The other species have been discovered in nature after an IUPAC code had been allocated to their synthetic analogs. The details for these materials are given in Table 8.

##### 3.1.1 Natural Aluminosilicate Zeolite Families

*Alcalime Family.* Table 9 lists all known aluminosilicate minerals with the ANA structure, with their compositions and type localities. It does not include all compositional variations, only those that have been given different mineral names.

*Chabazite Family.* Table 10 records details of the chabazite family.

*Gismondine Family.* Four minerals are accepted with the gismondine framework, again based upon variation of cation content and Si/Al disorder. These are listed in Table 11.

*Natrolite Family.* This family also contains four members distinguished by different Si/Al framework ordering and cation content, as shown in Table 12.

*Phillipsite Family.* Family details are in Table 13.

*Stilbite Family.* Details are in Table 14.

*Other Zeolites with Isotypic Frameworks (Listed in Table 15).* Heulandite and clinoptilolite share the same anionic framework and the differences between them have been the subject of much discussion, best summarized by Gottardi and Galli.<sup>14</sup> These authors suggest heulandite has

| *BEA <sup>a</sup> | Beta             | Tschernichite   | $\text{Ca}[\text{Al}_2\text{Si}_6\text{O}_{16}]\cdot 8\text{H}_2\text{O}$                                                                             | Neer Rd. Pit (Goble, Columbia County, Oregon, USA)                      |
| EAB               | TMA-E(AB)        | Bellbergite     | $(\text{K}, \text{Ba}, \text{Sr})_2\text{Sr}_2\text{Ca}_2(\text{Ca}, \text{Na})_4\text{Al}_{18}\text{Si}_{18}\text{O}_{72}\cdot 30\text{H}_2\text{O}$ | Bellerberg (also Bellberg) volcano, 2 km north of Mayen, Eifel, Germany |
| MFI               | ZSM-5            | Mutinaite       | $\text{Na}_3\text{Ca}_4\text{Si}_{85}\text{Al}_{11}\text{O}_{192}\cdot 60\text{H}_2\text{O}$                                                          | Mount Adamson Antarctica                                                |
| LOS               | Losod            | Bystrite        | $\text{Ca}(\text{Na}, \text{K})_7\text{Si}_6\text{Al}_6\text{O}_{24}\text{S}_{4.5}\cdot \text{H}_2\text{O}$                                           | Malo-Bystrinskoe deposit, Russia                                        |
| LTL               | Linde type L     | Perliaite       | $\text{K}_9\text{Na}(\text{Ca}, \text{Sr})[\text{Al}_{12}\text{Si}_{24}\text{O}_{72}]\cdot 15\text{H}_2\text{O}$                                      | Mounts Evelochorr and Yukspor (Khibina Massif, Kola Peninsula, Russia)  |
| NES               | NU-87            | Gottardiite     | $\text{Na}_3\text{Mg}_3\text{Ca}_5\text{Si}_{117}\text{Al}_{19}\text{O}_{272}\cdot 93\text{H}_2\text{O}$                                              | Mount Adamson Antarctica                                                |

<sup>a</sup>The asterisk denotes a well-defined framework subunit for which the pure end members have not been synthesized.<sup>11</sup>

**Table 9** The analcime family

| Mineral name         | Idealized unit cell composition                                                                   | Type locality                     | Comment                                                                                               |
|----------------------|---------------------------------------------------------------------------------------------------|-----------------------------------|-------------------------------------------------------------------------------------------------------|
| Analcime varieties   | $\text{Na}_{16}[\text{Al}_{16}\text{Si}_{32}\text{O}_{96}]\cdot 16\text{H}_2\text{O}$             | Isle of Cyclops (Catania, Sicily) | Ca, Mg-rich; <sup>a</sup> identified but not confirmed as distinct species (see also wairakite below) |
| Leucite <sup>b</sup> | $\text{K}_{16}[\text{Al}_{16}\text{Si}_{32}\text{O}_{96}]\cdot \text{H}_2\text{O}$                |                                   |                                                                                                       |
| Pollucite            | $(\text{Cs}, \text{Na})_{16}[\text{Al}_{16}\text{Si}_{32}\text{O}_{98}]\cdot n\text{H}_2\text{O}$ | San Piero in Campo (Sicily)       | Cs must be present in excess of 50% to be defined as pollucite                                        |
| Wairakite            | $(\text{Ca}, \text{Na}_2)_8[\text{Al}_{16}\text{Si}_{32}\text{O}_{98}]\cdot 16\text{H}_2\text{O}$ | Wairakei (New Zealand)            | Ca should be in excess of 50% to be defined as wairakite                                              |

<sup>a</sup>Mg-rich analcime has been described as doranite. <sup>b</sup>Also ammonioleucite,  $(\text{NH}_4, \text{K}_{16})[\text{Al}_{16}\text{Si}_{32}\text{O}_{96}]$ .

**Table 10** The chabazite family

| Mineral name     | Idealized unit cell composition                                                                         | Type locality                     |
|------------------|---------------------------------------------------------------------------------------------------------|-----------------------------------|
| Chabazite        | $\text{Ca}_6[\text{Al}_{12}\text{Si}_{24}\text{O}_{72}]\cdot 40\text{H}_2\text{O}$                      | Oberstein (Germany)               |
| Willhendersonite | $\text{Ca}_2\text{K}_2[\text{Al}_6\text{Si}_6\text{O}_{24}]\cdot 10\text{H}_2\text{O}$                  | San Venanzo Quarry (Terni, Italy) |
| Herschelite      | $\text{Na}_6\text{K}_2\text{Ca}_2[\text{Al}_{12}\text{Si}_{24}\text{O}_{72}]\cdot 36\text{H}_2\text{O}$ | Aci Castello (Sicily)             |

**Table 11** The gismondine family

| Mineral name | Idealized unit cell composition                                                        | Type locality                               |
|--------------|----------------------------------------------------------------------------------------|---------------------------------------------|
| Amicite      | $\text{K}_4\text{Na}_4[\text{Al}_8\text{Si}_8\text{O}_{32}]\cdot 10\text{H}_2\text{O}$ | Höwenegg (Hegau, Germany)                   |
| Garronite    | $\text{NaCa}_{2.5}[\text{Al}_6\text{Si}_{10}\text{O}_{32}]\cdot 14\text{H}_2\text{O}$  | Garron Plateau (Co. Antrim, N. Ireland)     |
| Gismondine   | $\text{Ca}_4[\text{Al}_8\text{Si}_8\text{O}_{32}]\cdot 16\text{H}_2\text{O}$           | Capo di Bova (Rome, Italy)                  |
| Gobbinsite   | $\text{Na}_5[\text{Al}_5\text{Si}_{10}\text{O}_{32}]\cdot 11\text{H}_2\text{O}$        | Gobbins Escarpment (Co. Antrim, N. Ireland) |

tetrahedral interstices. Kehoeite has the apparent composition  $(\text{Zn}, \text{Ca})\text{Al}_2(\text{PO}_4)_2(\text{OH})_2\cdot 5\text{H}_2\text{O}$  and has formerly been included in this category, but is now known to be a mixture of different minerals.

Lovdardite has a particular significance as it contains three-membered rings of linked tetrahedra, which also have been identified in synthetic zeolite-like substances.

### 3.3 Natural Zeolite-like Minerals with Incomplete Frameworks

Baerlocher, Meier, and Olson<sup>11</sup> have included materials in their listing in which the Si/Al tetrahedra do not share all four corners to complete a framework. These minerals have an appreciable content of hydroxyl groups located at

**Table 12** The natrolite family

| Mineral name   | Idealized unit cell composition                                                                             | Type locality                                   |
|----------------|-------------------------------------------------------------------------------------------------------------|-------------------------------------------------|
| Gonnardite     | $(\text{Na}_{10}\text{Ca}_4)[\text{Al}_{18}\text{Si}_{22}\text{O}_{80}] \cdot \approx 20\text{H}_2\text{O}$ | Chaux de Bergonne (Gignat, Puy de Dome, France) |
| Natrolite      | $\text{Na}_{16}[\text{Al}_{16}\text{Si}_{24}\text{O}_{80}] \cdot 16\text{H}_2\text{O}$                      | Hohentwiel (Hegau, Baden-Württemberg, Germany)  |
| Mesolite       | $\text{Na}_6\text{Ca}_5[\text{Al}_{16}\text{Si}_{24}\text{O}_{80}] \cdot 22\text{H}_2\text{O}$              | Nova Scotia (Canada)                            |
| Scolecite      | $\text{Ca}_8[\text{Al}_{16}\text{Si}_{24}\text{O}_{80}] \cdot 24\text{H}_2\text{O}$                         | None                                            |
| Paranatrolite  | $(\text{Na},\text{Ca})_{16}[\text{Al}_{16}\text{Si}_{24}\text{O}_{80}] \cdot 24\text{H}_2\text{O}$          | Mont Saint-Hilaire (Montreal, Canada)           |
| Tetranatrolite | $(\text{Na},\text{Ca})_{16}[\text{Al}_{16}\text{Si}_{24}\text{O}_{80}] \cdot 16\text{H}_2\text{O}$          | None                                            |

**Table 13** The phillipsite family

| Mineral name | Idealized unit cell composition                                                                                         | Type locality         |
|--------------|-------------------------------------------------------------------------------------------------------------------------|-----------------------|
| Harmotome    | $\text{Ba}_2(\text{Ca}_{0.5}\text{Na})[\text{Al}_5\text{Si}_{11}\text{O}_{32}] \cdot 12\text{H}_2\text{O}$              | Andreasburg (Germany) |
| Phillipsite  | $\text{K}_2(\text{Ca},\text{Na}_2)_2[\text{Al}_6\text{Si}_{10}\text{O}_{32}] \cdot 12\text{H}_2\text{O}$                | Aci Castello (Sicily) |
| Wellsite     | $\text{Ca}_{1.6}\text{Ba}_{0.4}(\text{Na},\text{K})[\text{Al}_5\text{Si}_{11}\text{O}_{32}] \cdot 13\text{H}_2\text{O}$ | None                  |

**Table 14** The stilbite family

| Mineral name | Idealized unit cell composition                                                                 | Type locality                                       |
|--------------|-------------------------------------------------------------------------------------------------|-----------------------------------------------------|
| Barrerite    | $\text{Na}_{16}[\text{Al}_{16}\text{Si}_{56}\text{O}_{144}] \cdot 52\text{H}_2\text{O}$         | Capo Pula (Sardinia)                                |
| Stellerite   | $\text{Ca}_8[\text{Al}_{16}\text{Si}_{56}\text{O}_{144}] \cdot 56\text{H}_2\text{O}$            | Komandar Islands (Bering Sea)                       |
| Stilbite     | $\text{Na}_4\text{Ca}_8[\text{Al}_{20}\text{Si}_{52}\text{O}_{144}] \cdot 56\text{H}_2\text{O}$ | Helgusta Iceland Spar Mine (Reydarfjordur, Iceland) |

tetrahedral corners. The justification for their inclusion as zeolite-like minerals arises from the recognition of the openness of their incomplete frameworks in which are recognizable zeolitic cavities and channels. Three minerals of these are aluminosilicates (partheite, roggianite, and wenkite) and the other is a beryllsilicate, chiavennite. Further details of these minerals are in Table 17.

**Table 15** Other isotypic zeolites

| Mineral name   | Idealized unit cell composition                                                             |
|----------------|---------------------------------------------------------------------------------------------|
| Heulandite     | $\text{Ca}_4[\text{Al}_8\text{Si}_{28}\text{O}_{72}] \cdot 24\text{H}_2\text{O}$            |
| Clinoptilolite | $(\text{Na},\text{K})_6[\text{Al}_6\text{Si}_{30}\text{O}_{72}] \cdot 20\text{H}_2\text{O}$ |
| Laumontite     | $\text{Ca}_4[\text{Al}_8\text{Si}_{16}\text{O}_{48}] \cdot 16\text{H}_2\text{O}$            |
| Leonhardite    | $\text{Ca}_4[\text{Al}_8\text{Si}_{16}\text{O}_{48}] \cdot 14\text{H}_2\text{O}$            |
| Dachiardite    | $\text{Na}_5[\text{Al}_5\text{Si}_{19}\text{O}_{48}] \cdot 12\text{H}_2\text{O}$            |
| Svetlozarite   | $\text{Na}_5[\text{Al}_5\text{Si}_{19}\text{O}_{48}] \cdot 12\text{H}_2\text{O}$            |

### 3.4 Further Information on Natural Zeolites and Related Species

It can be seen from earlier sections that some anomalies have arisen between the recognition of zeolite species by mineralogists and the characterization of their frameworks by crystallographers. Many mineralogists (amateur and professional) collect natural zeolite specimens because of their beauty and novel crystal habits. Both Tschernich<sup>13</sup> and Gottardi and Galli<sup>14</sup> have provided excellent texts covering the mineralogical properties of zeolites. These authors provide line drawings of zeolite crystal habit and details of their geological occurrences and genesis. Tschernich lists classical mineralogical physical and optical properties, as do Gottardi and Galli, who also provide details of cation sites and framework configuration. These authors also discuss, in detail, the interrelationships between the zeolite families as well as their chemistries and syntheses.

**Table 16** Naturally occurring zeotypes

| IUPAC framework code | Mineral name  | Idealized unit cell composition                                                                                             | Type locality      |
|----------------------|---------------|-----------------------------------------------------------------------------------------------------------------------------|--------------------|
| ANA                  | Hsianghualite | $\text{Li}_{16}\text{Ca}_{24}[\text{Be}_{24}\text{Si}_{24}\text{O}_{96}]$                                                   | Hunan (China)      |
|                      | Viseite       | $\text{Na}_2\text{Ca}_{10}[\text{Al}_{20}\text{Si}_6\text{P}_{10}\text{O}_{60}(\text{OH})_{36}] \cdot 16\text{H}_2\text{O}$ | Visé (Belgium)     |
| LOV                  | Lovdarite     | $\text{K}_4\text{Na}_{12}[\text{Be}_8\text{Si}_{28}\text{O}_{72}] \cdot 18\text{H}_2\text{O}$                               | Lovozero (Russia)  |
| RHO                  | Pahasapaite   | $(\text{Ca},\text{Li},\text{K},\text{Na})_{11}\text{Li}_8[\text{Be}_{24}(\text{PO}_4)_{24}] \cdot 38\text{H}_2\text{O}$     | None               |
| WEI                  | Weinebenite   | $\text{Ca}^{2+}_4(\text{H}_2\text{O})_{16}[\text{Be}_{12}\text{P}_8\text{O}_{32}(\text{OH})_8]$                             | Weinebene, Austria |

**Table 17** Zeolite-type minerals with incomplete frameworks

| –PAR                 | Partheite    | $\text{Ca}_8[\text{Al}_{16}\text{Si}_{16}\text{O}_{60}(\text{OH})_8] \cdot 16\text{H}_2\text{O}$                                    | Taurus Mts (Turkey)                     |
| –ROG                 | Roggianite   | $\text{Ca}_{16}[\text{Al}_{16}\text{Si}_{32}\text{O}_{88}(\text{OH})_{16}](\text{OH})_{16} \cdot 26\text{H}_2\text{O}$              | Alpe Rosso (Val Vigezzo, Novara, Italy) |
| –WEN                 | Wenkite      | $\text{Ba}_4(\text{Ca}, \text{Na}_2)_3[\text{Al}_8\text{Si}_{12}\text{O}_{39}(\text{OH})_2(\text{SO}_4)] \cdot 3\text{H}_2\text{O}$ | None                                    |

Tschernich provides a comprehensive list of outmoded zeolite mineral names. Table 18 gives examples of some of the more well known.

### 3.5 Synthetic Species

#### 3.5.1 Synthetic Aluminosilicate Zeolites

As mentioned earlier, pioneering work by Barrer showed that some natural zeolite species could be synthesized in the laboratory. This has led to many synthetic routes and to a proliferation of other species with novel structures not known in nature.

Table 19 lists all synthetic zeolites (included those analogous to naturally occurring ones) whose structures are confirmed in Baerlocher, Meier, and Olson.<sup>11</sup> Note that many are still described by acronyms related to their original source. In some cases, this is to the discoverer, for example, those synthesized for the first time by George Kerr from the Mobil Corporation have been given the code ZK. In other cases, the code relates to the company in whose laboratory the discovery was first made. Examples of this are ZSM, which comes from Zeolite Socony Mobil, and LZ, which relates to the Linde Company. Full explanations of these codes are available.<sup>15</sup> Table 19 also reflects the earlier confusion in the zeolite literature whereby claims to have discovered new materials were later discredited. It should also be remarked that often the isotopic structures reflect synthetic success in preparing analogs with differing Si/Al ratios, that is,

with various amounts of Al isomorphously substituting Si tetrahedral positions. The best-known examples of this can be seen in the synthetic faujasites Linde X and Linde Y and the high-silica zeolites exemplified by the BETA, EMC-2, EU-1, MAZ, MEI, MEL, MFI, MFS, MTT, MTW, NES, and TON frameworks. Their production reflects the high catalytic activity noted for silica-based structures containing very small proportions of isomorphously substituted Al. By the same token, synthetic analogs of natural species can be high-silica materials (e.g. as seen in CHA, ERI, FAU, FER, MAZ, and OFF variants).

#### 3.5.2 Synthetic Zeotypes

In 1983, workers at the Union Carbide (formerly Linde, now Union Oil Products (UOP)) laboratories in Tonawanda near New York reported a new class of microporous inorganic solids. Some materials were layered but, of the 20 new phases reported,<sup>16</sup> no less than 14 were framework compounds based upon three-dimensional arrays of linked  $[\text{AlO}_4]^{5-}$  and  $[\text{PO}_4]^{3-}$  coordination polyhedra. These novel zeotypes were designated by the acronym  $\text{AlPO}_4$ . As would be expected, the linkage of the Al/P tetrahedra created an uncharged framework and so no charge-balancing cations are present and the materials have water in the voids of the framework. Clearly these do not have the property of ion exchange expected from a zeolitic type material. Subsequent work demonstrated that many other closely related microporous materials could be synthesized with a wide variety of cations in the tetrahedral interstices, including those requiring a charge-balancing cation. Furthermore, a high proportion of these novel zeotypes have structures isotopic with some 15 natural and synthetic aluminosilicate zeolites. Table 20 lists synthetic zeotypes with unique frameworks and Table 21 classifies further examples according to isotopic aluminosilicate frameworks.

The acronyms used in these tables require further explanation. The known Aluminophosphate ( $\text{AlPO}_4$ ) structures also have a number (e.g.  $\text{AlPO}_4$ -5), or a further letter code (e.g.  $\text{AlPO}_4$ -D), appended. They are the labels given by the first literature report and have no scientific significance. Note that the ATT framework, coded as  $\text{AlPO}_4$ -12 TAMU, marks that the material was first synthesized at Texas A&M University. Similarly, those encoded as MCM are Mobil products. Apart from those that are self explanatory, such as gallosilicate ABW or beryllsilicate gismondine, the remaining acronyms

**Table 18** Some well known zeolites and their outmoded names

| Zeolite     | Outmoded name                                             |
|-------------|-----------------------------------------------------------|
| Analcime    | Analcite                                                  |
| Chabazite   | Acadialite, haydenite, phacolite, seebachite, herschelite |
| Epistilbite | Orizite, parastilbite, reissite                           |
| Gismondine  | Gismondite, zeogonite (with phillipsite)                  |
| Gmelinite   | Sarcosite                                                 |
| Laumontite  | Laumonite, scheiderite, sloanite, leonhardite             |
| Levyne      | Levynite, mesoline                                        |
| Mesolite    | Mesotype                                                  |
| Mordenite   | Arduinite, flokite, pseudonatrolite, ptilolite, steelite  |
| Natrolite   | Galaktite, mesotype, fargite, laubanite                   |
| Phillipsite | Christianite, wellsite                                    |
| Stilbite    | Desmine, epidesmiline, foresite                           |
| Thomsonite  | Comptonite, faroelite, mesole, mesotype                   |

<sup>a</sup>When synthetic analogs of naturally occurring aluminosilicate zeolites have been synthesized they are listed by the natural mineral names and their idealized compositions. <sup>b</sup>For \*BEA the asterisk denotes a well-defined structural subunit for which the pure end members have not been obtained. <sup>c</sup>The structures EMT and FAU also crystallize as a series of structural intermediates. <sup>d</sup>ERI and OFF also form as a series of structural intermediates.

in both Tables 20 and 21 denote zeotypes prepared by Union Carbide workers who have developed the following short-hand notation for framework materials in which tetrahedral positions accommodate atoms other than Si and Al.

1. Silicoaluminophosphates are described as SAPO, for example, the AFR structure assigned to SAPO-40 (see Table 20).

2. Metal aluminophosphates have the generic acronym MeAPO and metal aluminosilicophosphates are MeAPSO. More specific descriptions come by inserting the appropriate chemical symbol(s) into the code. There are many examples of this in Table 21, for example, AsPO-34, AsVBeAPO-34, CoAPO-34, MnAPSO-34, FeAPSO-44, and so on. The letters C, M, and Z are sometimes used

**Table 20** Synthetic zeotypes with unique frameworks

| IUPAC code | Name or acronym            | Idealized composition                                                                                                                                                                                              | Other isotypic synthetic zeotypes <sup>a</sup>  |

<sup>a</sup>Names as listed in Table 19.<sup>11,16</sup> See text for explanation of acronyms. <sup>b</sup>Recent evidence is that the Ti may well be hexacoordinate in this and related materials. <sup>c</sup>A recent report suggests that roggianite has some Be in framework sites.<sup>11</sup> Note: Framework constituent luminophosphate, (FCAPO).

as shorthand for the elements chromium, magnesium, and zinc, respectively.

- When wide compositional ranges can be prepared as isomorphous substitutions into aluminophosphates, two generalized acronyms are used: (a) FCAPO, where FC means framework constituents, and encompasses structures containing proportions of As, Be, B, Cr, Ga, Li, and V; (b) Aluminophosphate containing Fe, Ti, as T atoms (XAPO), where Fe or Ti are in combination with Co, Mg, Mn, or Zn. Further examples of compositional variations in the unique zeotype frameworks listed in Table 20 are given in Table 22. It should be noted that not all these compounds have been fully structurally characterized at the time of writing.

The material designated AlAsO<sub>4</sub>-1 comprises linked [AlO<sub>4</sub>]<sup>5-</sup> and [AsO<sub>4</sub>]<sup>3-</sup> tetrahedra.

Finally, it must be mentioned that catalytic interest has promoted the preparation of many high-silica zeolitic-like phases modified to include other T atoms such as B, Ti, Fe, or Ga. This modification can be at synthesis, or by postsynthesis treatment to replace Si and/or Al from existing high-silica frameworks. Not all these are recorded here because these modified materials again may not be fully characterized; however, Table 21 lists well-characterized examples, for example, analogs of the MFI (ZSM-5) framework.

### 3.5.3 Phases of Silica with Open Zeolite-like Frameworks

Synthetic studies on high-silica zeolites showed that silicon end members of structural groups could be prepared. Clearly these are pure silica phases and to date several have been prepared including a synthetic analog of the natural silica phase melanophlogite. These are listed in Table 23. They have sometimes been described as clathrasils, in deference to their strong structural links to clathrates as can be seen from their soap-bubble like frameworks (illustrated in Figure 12).

### 3.5.4 Felspathoid Frameworks

Earlier discussion introduced the concept of using the characteristic truncated octahedral elements of the sodalite framework to explain the molecular architecture of the synthetic zeolites X and Y (see Section. 2.4.3). There are other structural correlations that can be drawn between felspathoids and zeolites, for example, that the cancrinite cage (11-hedron) is a face-sharing element seen in the LTL, ERI, OFF, and LOS frameworks. Furthermore, in nature, salt ion pairs are contained in felspathoid minerals and when these are removed the residual framework exhibits the zeolitic properties of ion exchange and reversible water loss. Other similarities arise in that zeolites can imbibe salt ion pairs, and isotypic structures

with T atoms other than Si and Al are known in both natural and synthetic feldspathoid analogs.

Table 24 lists feldspathoid frameworks included in Baerlocher, Meier, and Olson.<sup>11</sup>

## 4 ZEOLITE GENESIS

### 4.1 Natural Species

#### 4.1.1 Introduction

Most mineralogical displays in museums contain zeolite specimens because of their large attractive crystals and regular

crystalline habit. These are of volcanic origin, which, until comparatively recent times, was regarded as their predominant mode of genesis. This view changed dramatically in the early 1960s when several of the major oil companies sent out survey teams into the western United States. These teams were hopeful of finding zeolites of sedimentary origin that might be of sufficient purity to be of commercial value. In fact, reports as early as 1891, from the first ever oceanographic survey (1873–1876) made by *HMS Challenger*, had described zeolites in ‘red mud’ recovered from the bed of the Pacific Ocean, and in 1914 Johannsen had reported fine-grained zeolites in beds of volcanic tuffs in Colorado, Wyoming, and Utah in the USA.

The survey teams subsequently identified many large-scale sedimentary zeolite deposits and today these are known to occur worldwide in vast quantities. The occurrences vary from those of high zeolite purity (>90%), such as those located in California, to tuffaceous materials of around 50–60% zeolite content (as in Italy). Commercial mining operations are known in USA, Japan, Cuba, Italy, Hungary, Bulgaria, Czechoslovakia, Indonesia, Korea, Russia, and South Africa. Workable deposits also exist in Mexico, Greece, and other Balkan states.

It has been reported by F.A. Mumpton<sup>17</sup> (1978) that more than 1000 occurrences of zeolite minerals in over 40 countries have been discovered since 1950. In addition to the hydrated aluminosilicate species, new minerals related to zeolites have been discovered, including the porous clathrasils such as Melonophlogite (a silica only framework). Species in which the aluminum or silicon has been replaced by other elements (such as phosphorus, iron, and beryllium) have also been discovered as exemplified by viscite, a silicoaluminophosphate related to analcime. At the present there are 38 different natural framework topologies, as shown in Table 25.

It is now recognized that natural zeolites arise from a wide variety of geological events and these will now be briefly discussed. Gottardi<sup>18</sup> and Tschernich<sup>13</sup> have reviewed these in more detail.

#### 4.1.2 Formation of Zeolites in Nature

Zeolites arise naturally by broadly two routes, one predominantly at low temperatures (below 40 °C) and associated with sedimentary processes, with the second being at higher temperatures and linked to volcanic and associated thermal processes.

##### Low-Temperature Diagenic Routes to Zeolite Formation.

1. Land processes. Strictly, the majority of diagenic routes are also associated with vulcanism because they are a consequence of alteration processes to wind-blown glassy volcanic ashes or layers of pyroclastic tuffs. Alteration can be in a hydrologically open system when percolation of meteoric water through tuff layers

creates a series of zeolitized zones. The deeper zones contain, successively, zeolites such as clinoptilolite, mordenite, chabazite, phillipsite, and analcime. (The name clinoptilolite will be used throughout the rest of this article to signify silica-rich, alkali metal forms of heulandite as this is the preferred designation in most literature references to this material.) Typical examples of this are in the John Day Formation (Oregon, USA) and at Oahu (Hawaii). At some locations (e.g. in Japan), similar zeolite zoning is linked to burial diagenesis where pressure and temperature effects have contributed to the formation of zeolites in underlying zones, with the lowest zones containing the most dense zeolite (e.g. analcime).

Hydrologically closed systems also create zeolites when glassy volcanic ash falls into a saline lake under arid, or semiarid, conditions. Conditions of high pH and salt concentration arise from evaporation, producing ideal conditions for zeolites to form. Lake Tecopa, California, and Lake Magadi in Kenya contain zeolites formed in this way. The silica source in this route is not confined to glassy ash and can be clays, plagioclases, or even biogenic silica.

Finally, some soils contain relatively high proportions of zeolites ( $\approx 15\%$ ). These result again from arid or semiarid environments where evaporation produces a high concentration of sodium carbonate, which can alter clay minerals to produce zeolites. Examples of this are the heulandite found in the Harwell soil series in Southern England and the analcime in the San Joaquin Valley (California).

2. Marine processes. Sea water reacts with ocean-bed sediments containing volcanic ash, or biogenic silica from Radiolarians, to form zeolites. This process is common in deep-sea sediments and phillipsite makes up 80% of the sediment in the Indian and Pacific Oceans. Clinoptilolite is abundant in Atlantic sediments and both phillipsite and clinoptilolite are found in manganese nodules on the ocean beds.

Zeolites created in shallow sea sediments are also widespread. Other marine zeolites include analcime, merlinoite, chabazite, stilbite, and more rarely, erionite, mordenite, and laumontite. Figure 13 shows a schematic of the zoning patterns of autogenic zeolites and feldspars in tuffs of saline alkaline lakes, saline alkaline soils, deep-sea sediments, open hydrologic systems and burial diagenesis

*Hydrothermal Routes at Higher Temperatures.* Zeolites are commonly found in veins or cavities in volcanic rock as a result of the alteration of cooling lava flows coming into contact with surface water. Hot thermal salt solutions are created that circulate through the flow, dissolving out glass to form zeolites. Examples of this mode of occurrence occur in basalts and are common at many locations throughout the world. Zeolites arise in pegmatites from late-stage

**Figure 13** Schematic representation of zoning patterns of autogenic zeolites and feldspars. (Reprinted from Ref. 17. © 1978, with permission from Elsevier)

crystallization involving alteration of pegmatic minerals, and also ultimately when silica-rich hot water is expelled, which then alters surrounding rocks to zeolite phases. Examples of this can be seen in the Elba granodiorites (Italy) and in the borolanite found near Altnahara (Scotland).

Hydrothermal ore deposits can contain local zeolites (e.g. the Andreasburg sulfide deposit in Germany) arising from circulating hot fluids. Similarly, zeolites arise in hydrothermal veins and cavities in felspathic rocks like the Adamello granite in Italy.

Geothermal fluids are a common agency for zeolite formation and this has been well documented in Iceland, at Wairakei (New Zealand), and in Yellowstone Park (USA). Often, well-defined zones (illustrated for Iceland in Figure 14)

can be identified with, say, clinoptilolite and mordenite at shallow (cooler) depths with deeper (hotter) environs containing heulandite, laumontite, and then wairakite and analcime. These assemblages feature a continuous transition to burial diagenesis.

*Other Routes.* When heat from a magma chamber, or an intrusive dyke, bakes surrounding rocks, zeolites can be part of the suite of minerals produced in zones via this process of contact metamorphism. This sequence has been identified in the Rhodope Mountains of Bulgaria. Bulgaria also has been cited as the location of proposed geoautoclaves, where enclosed conditions of high temperature and vapor pressure

**Figure 14** Temperature zoning of zeolites occurring in geothermal areas of Iceland. (Reprinted from Ref. 17. © 1978, with permission from Elsevier)

exist in an ignimbrite immediately after the deposition and zeolites are formed as a consequence.

In all the modes of formation discussed, zeolites are clearly secondary minerals, that is, created by alteration of existing rocks. Only analcime and natrolite have been suggested as primary minerals, that is, ones created by direct magmatic crystallization. This issue is still in doubt but may be true for analcimes from the Crowsnest Formation, Alberta, Canada, and the Colima lavas of Mexico.

## 4.2 Synthetic Species

### 4.2.1 Introduction

The progress of laboratory synthesis of zeolites first followed the high temperature and pressure experiments

conceived by Barrer to mimic the then perceived geological genesis. With the wider realization of the sedimentary route to the formation of zeolites came studies at lower temperature, hydrothermal, conditions (e.g. by R. M. Barrer in the UK and R.M. Milton and D.W. Breck of the then Union Carbide laboratories in New York State). In 1948, Barrer<sup>19</sup> reported the first confirmed synthesis of a zeolite, in which he had produced a synthetic zeolite with no known natural counterpart, Zeolite P. In this first paper, Barrer documented the fundamental methodology that is still used today in exploratory zeolite synthesis:

- The effect of the reaction gel composition on crystallization product
- The effect of pH on crystallization
- The effect of temperature and time
- The nature of the starting materials

Early work concentrated on the use of inorganic cation-based formulations but both Barrer and Kerr (Mobil) pioneered the use of organic cations as ingredients for zeolite synthesis. This approach later produced the industrially significant high-silica zeolites, such as ZSM-5, and the explosion of zeotypes listed in the previous section. Some of these materials can even be best made at subambient temperatures. Another significant change of recent origin is that of the substitution of the  $F^-$  ion for  $OH^-$  as the so-called mineralizer in zeolite synthesis.

The facile way by which zeolitic frameworks can be formed is further confirmed by their production under acid and nonaqueous conditions, from the gas phase, and with organic additives as diverse as simple alcohols<sup>20</sup> and amines, polymers, crown ethers, and dye molecules.

#### 4.2.2 Outline of Zeolite Synthesis

Figure 15 presents a general view of the elements of zeolite synthesis. There are a number of factors, which affect zeolite crystallization:

- Silica/alumina sources
- Hydroxide and/or fluoride concentration
- Cations (both organic and/or inorganic)

**Figure 15** Schematic of the steps typical in zeolite (zeo-type) syntheses

- Anions (other than  $OH^-$  or  $F^-$ )
- Water content of gel
- Time
- Reaction temperature (ambient  $\sim 40^\circ\text{C}$ , low  $\sim 110^\circ\text{C}$ , moderate  $150^\circ\text{C}$  and high  $>200^\circ\text{C}$ )
- Reaction gel ageing
- Stirring
- Nature of mixture (gel, sol, or solution)
- Order of reagent mixing

Several zeolites crystallize with a fairly narrow range of Si/Al ratios, for example, Zeolites A, X and Y. However other materials like the pentasil (ZSM-5 or ZSM-11) can be produced over a wide range from ratios of 7.5 to infinity and sodalite from ratios of 1 to infinity. Attempts to change the Si/Al ratio of the final product by changing the ratio in the reaction gel often leads to cocrystallization of different zeolite types. The source of the silica and/or alumina can also affect the final product. A very wide range of silica sources have been used including natural materials such as kaolinite, volcanic glasses, rice husks, and nepheline, but most laboratory and industrial preparations use an 'active silica'. This is either a silicate, hydrated silicate, or a dispersion of high surface area silica (i.e. a silica sol.).

Aluminium sources have also been very varied and include aluminium wire, metal aluminates, aluminium alkoxide, and aluminium oxides and hydroxides. For zeotype synthesis, boehmite, a reactive aluminium oxide/hydroxide, is the preferred source with phosphoric acid providing the phosphorus content. In zeolite synthesis, if the hydroxide content is increased there is generally an increase in crystallization rate, which can be beneficial. However it must be remembered that if a number of different zeolites can crystallize from one reaction mixture with only time being the separating variable then the use of increased hydroxide can lead to cocrystallization and impure final products. The cation source can be one or more alkali metal cations, less frequently an alkaline earth cation, or an organic cation (e.g. Tetramethylammonium (TMA)). The main role of inorganic cations is to balance the negative charge created on the zeolite framework with the incorporation of  $Al^{3+}$ . As space is limited, if a monovalent cation replaces a divalent cation then we tend to see a reduction in the aluminium content of the zeolite framework. In addition to charge balancing, inorganic cations can also influence the framework structure formed, as seen in Table. 26.

It has been found that organic agents present in the gel can have a profound influence on syntheses, especially for zeotypes and high-silica species. Organic cations can interact with the reaction gel in a number of ways. They can

- act as templating of structure-directing agents
- act as gel modifiers, allowing higher silica/alumina ratios to be achieved for particular zeolite structures than could otherwise be obtained.
- interact with the gel affecting alkalinity

**Table 26** Some zeolite syntheses in relation to inorganic cation content

| Zeolite         | Cations in Reaction Mixture                                                                                   | Preferred               |
|-----------------|---------------------------------------------------------------------------------------------------------------|-------------------------|

| XK-5 types      | Ba, Na + Ba, K + Ba,<br>Li + Cs + NMe <sub>4</sub>                                                            | Ba                      |
| ZSM-2 type      | Li + Cs + NMe <sub>4</sub>                                                                                    | Li                      |

- interact physically affecting the gelling process
- act as void filler, similar to water and indeed replacing water as the main void filler in nonaqueous systems.

Examples of their structure-directing influence can be seen in Table 27. This is a restricted list and Szostak has provided a comprehensive survey.<sup>15</sup>

The primary reagents are combined in an OH<sup>-</sup> medium and the gel, so-formed, held at defined temperatures and pressures for the crystallization period (Figure 16). Gel ageing prior to this crystallization time can be needed. More recent syntheses have shown that high-silica zeolites prepared with a F<sup>-</sup> mineralizer are almost fault-free, unlike those prepared in OH<sup>-</sup> media.<sup>22</sup>

Comprehensive texts exist covering all aspects of zeolite synthesis methodology, and those by Barrer,<sup>23</sup> Jacobs and Martens,<sup>24</sup> and Szostak<sup>25</sup> are especially useful and for a recent historical survey the reader is directed to the review by Cundy and Cox.<sup>26</sup>

#### 4.2.3 Mechanism of Zeolite Synthesis

Researchers have attempted to elucidate the mechanism for zeolite formation for over 50 years. Two directions of experimental work have been examined:

- Identification of species during the crystallization process;
- Monitoring of the crystallization kinetics.

There are a number of different factors that can operate in a crystallizing gel and these have been summarized by Sand:<sup>27</sup>

- Precipitation of the gel
- Gel dissolution
- Zeolite nucleation
- Crystal growth of the zeolite nuclei
- Dissolution/recrystallization of metastable phases (Oswald's Law of successive transformations)
- Formation of more stable phases
- Successive nucleation, crystal growth, and further nucleation
- Formation of the equilibrium phase.

A number of analytical techniques have been used to identify the species present in the reaction gels. These

include chemical analysis of the various phases, powder X-ray diffraction analysis to identify the crystal structure, IR spectroscopy to help identify substructural species early in the nucleation phase. Thermal analysis to yield information on the degree of hydration and thermal stability, and electron microscopy to give information on crystal shape and size. Other techniques are now also being used such as NMR, which with the advent of Magic angle spinning nuclear magnetic resonance (MAS-NMR) can now analyze both the reaction gel/solution and the final solid zeolite product. The combination of X-ray methods providing data on the long-range order and NMR providing short range order of the crystal-structure data ensures that these two methods are very powerful complementary techniques.

It is anticipated that the continued application of sophisticated NMR spectroscopy to solution and solid phases with the development of diffraction techniques to study the early stages of zeolite crystallization may ultimately clarify the problems of the mechanisms whereby zeolites are formed.

There have been two main schools of thought regarding synthetic zeolite formation: on the one hand it was considered that the crystallization process only occurred in the solution phase, with the gel just acting as a nutrient source. On the other it was proposed that there was direct hydrogel transformation. Different experimental work has supported both ideas.<sup>28,29</sup> Recently work on ZSM-5 has thoroughly investigated its formation,<sup>30</sup> and two processes have been proposed type 'A' and type 'B'. Type 'A' occurs in highly alkaline media with a polymeric silica source depolymerizing to yield negatively charged monomers that condense aluminate species around organic cations; this is a solution process. In type 'B', we start with monomeric silica in the reaction gel and the fast nucleation rate leads to direct hydrogel transformation, with any dissolved silica species being incorporated into the solid product last. Subotic<sup>31</sup> has proposed a kinetic model to discriminate between the two mechanisms. Formation of zeolite material has been shown to occur from pH values of 2.6 (for fluoride based media) to 14 (for hydroxide based media), over a wide range of Si/Al ratios. In many instances the same zeolite product can be produced from clear solutions, gels, and solid phases, while some zeolites can only be formed with difficulty over narrow compositions, temperatures, and times. This leads one to believe that no single mechanism exists to explain zeolite formation.

The stages shown above in Figure 15 are meant to imply that zeolite crystallization proceeds via a cooperative equilibrium interaction between the gel and species in solution rather than that whereby the gel reorganizes itself without influence from the liquid phase. This emphasizes two important concepts: firstly, that water plays a critical role in the zeolite framework genesis and, secondly, the function fulfilled by OH<sup>-</sup> (or F<sup>-</sup>) in providing control of pH, and gel chemistry, to facilitate the production of precursors germane to the building of frameworks via SBUs (Figure 2).

The role of the cations and organic agents can now be imagined as that of organizing water structures around which the subunits of structure assemble themselves. Earlier concepts described this as a templating effect, which envisaged close correlation between the sizes of hydrated cations, or organic entities, and the production of specific sizes or shapes in the microporous frameworks obtained. Experience has shown that specific templating is rare, such as that of TPA-OH in directing ZSM-5 synthesis and the use of 1,4-diazabicyclo[2,2,2]octane (DABCO) polymers in preparing gmelinite and mordenite structures. In the latter case the size of the polymeric unit controls the zeolite produced. The modern view tends to that of a guest agency (organic or inorganic) encouraging the formation of a water clathrate as a former for zeolite or zeotype structures. This simplistic approach needs to be extended to include the role of the cation species in pH control and the ability of all agencies to stabilize the various zeolite-like frameworks in the gel crystallization stage.

#### 4.3 Industrial-scale Synthesis of Zeolites

Industrial production of synthetic zeolites gives fine powders (<10 µm) in their sodium exchanged form. These materials can be used 'as synthesized', such as for use as detergents, and Figure 16 is a schematic diagram of the production of zeolite LTA (Na form) for this purpose. The manufacture of the synthetic faujasite (FAU) zeolite Y for catalytic uses follows a similar route.

Today there are three processes used industrially: hydrogel, clay conversion, and 'other' such as volcanic glass conversion. The first commercial process for preparing zeolites on a large scale was based on the hydrogel procedures developed in the laboratory. Here reagents included sodium silicate, sodium aluminate, and sodium hydroxide solutions. The hydrogel process is further classified into processes that use homogeneous gels, processes based on heterogeneous gels (here one reagent is a solid while the rest are usually liquids) and finally the gel-preform process, in which the aluminosilicate is formed into a pellet prior to crystallization to a zeolite. This produces 'binderless' zeolite aggregate. If possible, reaction temperatures are kept just below 100 °C and the crystallization is monitored by in situ XRD and/or spectroscopic methods. The mother liquor left over after crystallization is recycled but the number of cycles is limited owing to the increased chances of cocrystallization of unwanted side products. To use zeolites as desiccants and specialized sorbents, the fine powders need to be modified, prior to use, by agglomeration (and often ion exchange). The crystallites are invariably bound together with clay minerals, such as sepiolite, attapulgite, or kaolinite (as beads or extrudates), that make up 10–20% of the final composite. The major clay-type material used in the manufacture of zeolites is kaolin. For Zeolites A and X, in the clay conversion process manufacture the kaolin is generally dehydroxylated to form metakaolin by calcining in air at 550 °C. For Zeolite Y,

the kaolin is heated to 925 °C to form a defect spinel. These intermediate products are subsequently treated with sodium hydroxide, which creates the required zeolite, so linking the existing crystallites into an aggregate suitable for industrial use. If the zeolite is to be used as an Fluidized bed cracking catalyst (FCC) catalyst, then it is spray dried to yield particles of around 60 µm. For other applications, a larger particle size maybe required and here oil-drop or extrusion techniques are used.<sup>32</sup>

#### 4.4 Mesoporous Silicas

In 1992, Mobil workers<sup>33</sup> reported that they had prepared two mesoporous silicas, MCM-41 and MCM-48. These phases are related to the mineral silica species imogolite and marine diatoms. MCM-41 is a hexagonal structure while MCM-48 is a cubic one, and these two names actually represent families of materials. The pore sizes of these materials can be affected by which surfactant is used as the structure-directing agent during synthesis. To indicate pore sizes, the materials are usual labelled as MCM-41 (38), with the 38 representing the pore size of 38 Å. The MCM-41 family is composed of large diameter tubes, organised into an hexagonal array. It is interesting to note that the actual tube walls are amorphous silica (and/or alumino/silica) and can vary in thickness making them very different to zeolitic materials. These materials are normally prepared by cohydrolysis of tetraethylorthosilicate and a surfactant molecule like cetyltrimethylammonium hydroxide, an organo-aluminium or other organo-metal salt can also be introduced at this stage. Varying the amount and size of surfactant in the gel will change the nature of the pore structure in the crystallized product.

### 5 ZEOLITE PROPERTIES

#### 5.1 Stability

Thermal and hydrothermal stability varies widely with both zeolite species and cation content, larger cations tending to make the zeolite structure less stable. It should be noted that, geologically speaking, zeolites are metastable species and interconversions in both natural and synthetic species are common, for example, synthetic gismondine (NaP) crystallizes as a cubic form but on standing at room temperature changes to the tetragonal form. Despite this variation, it should be commented that the zeolites used for catalytic purposes are very stable under the conditions of the industrial processes used. Similarly, zeolites used as sorbents and desiccants have very long useful lives. In a static application, the lifetime, to all intents and purposes, are indefinite and in a dynamic circumstance; where a regeneration process is carried out, the lifetime period should still be about five years.

Zeolites are generally very chemically stable and well able to withstand poisoning by nitrogen and sulfur compounds. Their acid stability, however, is dependent on their Si/Al ratio, with those zeolites having Si/Al ~ 1 being unable to withstand pH < 4 and those with Si/Al > 5 being usefully acid resistant in mineral acids. The loss of intracrystalline water may result in structure collapse to an amorphous phase, for example, BaA loses water between 100–180 °C then collapses above 180 °C. Alkaline stability is good up to around pH 11 and zeolite frameworks are stable to  $\beta$ -,  $\alpha$ -, and  $\gamma$ -radiation, with only minor damage arising from prolonged exposure to neutron beams.

#### 5.2 Zeolite Surfaces

It is important to realize that useful zeolites have large internal surfaces, that is, a reminder of the 'sponge' analogy, and it is *these* surfaces that control their observable surface properties. Normally, surface areas of inorganic materials are quantified by standard gas sorption techniques, for example, N<sub>2</sub> uptake analyzed by Brunauer, Emmett, and Teller (BET) isotherm plots, and zeolites have nitrogen surface areas in the approximate region 100–1000 m<sup>2</sup> g<sup>-1</sup>. These estimates should be considered with caution because:

1. the precalcination step, required before N<sub>2</sub> uptake, can cause structural change,
2. the probe molecule may not have access to all the channels and cavities in the zeolite structure and, most importantly,
3. the value for the surface area obtained depends upon the assumption of monolayer coverage as required by BET theory.

A better view of the extent of the void volume available within a zeolite comes from simple measurements of water content as listed in Table 28. Zeolites with high voidage (e.g. LTA, CHA, FAU) can be assumed to have only 1% of their useful surface on the exterior of the crystal.

One final generalization about zeolite surfaces is to mark the presence of OH groups on internal and external surfaces despite the presumption of the three-dimensional nature of zeolite architecture arising from full corner sharing of Si/Al tetrahedra. The concentration of these OH groups in synthetic species is usually low (about 2 nmol g<sup>-1</sup>), but note the inclusion of incomplete framework structures in Baerlocher,

**Table 28** Void fractions of some zeolites assessed from their water content<sup>34</sup>

| Natural species | Void fraction | Synthetic species | Void fraction |
|-----------------|---------------|-------------------|---------------|
| Analcime        | 0.18          | ZSM-5             | 0.10          |
| Mordenite       | 0.28          | L                 | 0.32          |
| Clinoptilolite  | 0.34          | A                 | 0.47          |
| Gmelinite       | 0.44          | Y                 | 0.48          |
| Chabazite       | 0.47          | X                 | 0.50          |

Meier, and Olson's compilation<sup>11</sup> (see Tables 16, 17, and 20). The OH groups are in highest concentration in synthetic high-silica zeolites and, in ZSM-5 for instance, have been identified as terminal and bridging entities. The presence of these OH groups has great significance in zeolite catalysis and modification, as will be briefly reviewed later.

### 5.3 Ion Exchange

#### 5.3.1 Background

The identification of charge-balancing cations in crystallographically well-defined structures that change very little during cation-exchange processes has attracted the use of zeolites as models for the testing of the theory of ion exchange. This is true for both the equilibrium and kinetic aspects of the phenomenon.

Zeolites can have very high selectivities for specific cations but a full understanding of all the factors involved in delineating these selectivities has not yet been reached. Detailed consideration of this topic, and ion-exchange kinetics, are not appropriate here and has been reviewed elsewhere.<sup>35</sup>

Nevertheless, it is useful to point out that zeolites with higher framework Si content generally prefer larger, less hydrated cations (e.g. Cs with its smaller hydrodynamic radii), while those with Si/Al  $\sim 1$  take up hydrated polyvalent cations selectively. The role of water is apparent here and also with the growing realization that water in immediate contact with an aluminous zeolite surface is hydrolyzed with two foreseeable consequences:

1. the production of  $\text{OH}^-$ , which can lead to precipitation of metal oxides/hydroxides on the surface (e.g. Zn on LTA<sup>36</sup>)
2. immediate cation exchange, with  $\text{H}_3\text{O}^+$  entering the zeolite phase.

The latter process seems to be very selective against alkali metal cations in the initial stages of exchange and is critically dependent on alkali metal solution phase concentration.<sup>37</sup> Sometimes ion-exchange processes can be described as ion sieving when a particular cation (hydrated or unhydrated) is too large to enter all, or part of, the zeolite internal structure.

#### 5.3.2 Ion-exchange Applications

**Detergency.** The largest-scale industrial production of zeolites is that devoted to the production of the sodium form of zeolite A (LTA) for use in the detergent industry. This uses currently in excess of 0.5 million metric tonnes per annum worldwide. Zeolite A (NaA) is added to washing powders and other household detergents or cleansing powders as a water softener (described by the detergent industry as a builder). It

has a high selectivity for  $\text{Ca}^{2+}$  (less so for  $\text{Mg}^{2+}$ ) following the simple theory outlined in Section. 5.3.1.

The advantage of zeolite builders comes in their use as a replacement (sometimes only partial) for sodium tripolyphosphate, hence reducing the release of phosphates to the environment. An earlier Section. (4.3) showed the schematics of a production process for detergent grade A. It is interesting to record that the technology includes the 'design' of NaA crystals without sharp edges or corners to encourage their early removal from fabrics in the washing cycle. The release of NaA to the environment has been shown to be acceptable (Dyer<sup>38</sup> discusses the hazard assessment of this and other zeolites). The natural zeolites clinoptilolite and chabazite also are used as detergent builders.

**Radioisotope Scavenging.** Clinoptilolite has a relatively high Si/Al ratio and has the ability to scavenge cesium radioisotopes from aqueous nuclear wastes. An example of its industrial-scale use is in the development of the site ion-exchange effluent plant (SIXEP) by British Nuclear Fuels at their Sellafield site.<sup>39</sup> This uses a clinoptilolite, from Mud Hills, California, and meets the stringent performance requirements. The Cs selectivity of clinoptilolite has led to its possible use to reduce Cs radioisotope body burdens in sheep, and mordenite has been studied for the same use in reindeer. Mordenite also has been used to treat aqueous nuclear waste, as has an acid washed chabazite (AW500).

Clinoptilolite amendments to soil have greatly reduced cesium uptake by plants (e.g. on Bikini Atoll) and clinoptilolite from the Belli Plest deposit in Bulgaria was dropped by air to help control the Chernobyl accident. Finally, both zeolite A and a chabazite played key roles in the Three Mile Island clean-up program, again to scavenge Cs radioisotopes.

**Waste-Water Treatment.** There is a requirement in wastewater treatment to remove the ammonium ion and clinoptilolite has an appropriate selectivity for this ion. This zeolite is used in municipal sewage treatment in the USA and Hungary, and in Japan for cleaning up water from fish farms. The Italians have used chabazite-rich tuffs for a variety of water treatments.

These and other uses of natural zeolites have been reviewed.<sup>40</sup>

**Agriculture and Horticulture.**<sup>40</sup> There is a considerable literature relating how natural zeolites, and occasionally synthetic species, can be fed to various animal species (sheep, pigs, beef cattle, horses, and so on) with advantage. The benefits probably arise from a pH control effect in the animal gut (i.e. an ion-exchange phenomenon), and produce improved weight gains and disease reduction.

Other publications describe how the quality of soil can be improved by a 5–10% zeolite addition, followed by an increase in crop yield. This can be related to the zeolite acting as a controlled release fertilizer based upon an ammonium selectivity.

The zeolite most studied in both these areas is, again, clinoptilolite.

## 5.4 Sorption and Separations on Zeolites

### 5.4.1 Background

When the inherent water has been removed from a zeolite, the remaining voidage often has a useful capacity to take in guest molecules. Removal of water is described as activation and can be achieved by heating to about 350 °C. Industrially this is usually in combination with an applied vacuum or an inert gas purge. The guest molecules enter the internal regions of the zeolite host crystal through restricted dimensions prescribed by the oxygen atoms of the zeolite framework. Zeolite A (LTA; Figure 3) provides an example of this in that entry to the large cavity is via an S8R (crystallographic diameter 4.1 Å) and to the smaller sodalite unit through a S6R (crystallographic diameter 2.3 Å).

### 5.4.2 Uses of Zeolites as Molecular Sieves

Dimensions are comparable to molecular sizes and so zeolites can behave as molecular sieves. Indeed, this term is widely used to describe commercially available zeolites as typified by the well known Linde Molecular Sieves whose manufacture was pioneered by the Linde Corporation (latterly Union Carbide and now UOP) in New York State. These are sold as 3A, 4A, and 5A and are, respectively, the potassium, sodium, and calcium exchanged form of zeolite A, where the numbers represent their effective pore sizes in angstroms. Table 29 shows examples of the oxygen rings (windows) governing access into zeolites, with an indication of their sizes and the types of molecules able to pass through them. Note that the crystallographically measured ring sizes are not the same as their effective pore sizes. This arises principally from the thermal flexing of the aluminosilicate framework ( $\pm 0.3$  Å) and the inherent polarizability of organic molecules (i.e. their ability to be 'squeezed' through the window). Again zeolites have been popular models for sorbent theory, as described comprehensively in books by Barrer<sup>41</sup> and Ruthven.<sup>42</sup>

The separation of molecules on the basis of size has high potential at research and commercial levels. Many separations have been described<sup>34,40</sup> and the most well known are described in the following sections. It should also be pointed out that the technology exists whereby pore dimensions of zeolites can be modified by silanation or boranation. This can be done to achieve highly specific separations and/or gas encapsulation. Details are in the monograph written by Vansant.<sup>43</sup>

**Desiccants.** The ion-exchanged forms of zeolite A are well known as general laboratory and industrial drying agents in the form of extrudates or beads. The success of these

**Table 29** Zeolite molecular sieving, correlation between oxygen ring diameter and molecules admitted<sup>a</sup>

| Crystallographic dimension (Å) | No. of oxygens | Zeolite    | Examples of molecules admitted                                         |
|--------------------------------|----------------|------------|------------------------------------------------------------------------|
| 2.3                            | 6              | A, X       | H <sub>2</sub> O, NH <sub>3</sub>                                      |
| 3.8 <sup>b</sup>               | 8              | Chabazite  | He, Ne, Ar, CO <sub>2</sub>                                            |
| 4.1                            | 8              | A          | C <sub>2</sub> H <sub>2</sub> , MeNH <sub>2</sub>                      |
| 4.2 and 5.4                    | 10             | Ferrierite | As through S8R                                                         |
| 7.4                            | 12             | X, Y       | Cyclohexane, benzene, CCl <sub>4</sub> , B <sub>5</sub> H <sub>9</sub> |

<sup>a</sup>Two zeotypes have larger rings, VPI (18SR, 12.1 Å) and cloverite (20 SR, 13 × 4.0 Å); see Table 2 for other details. <sup>b</sup>Distorted.

materials as desiccants arises from several possible reasons, viz.:

1. their ability to exclude other molecules on the basis of size;
2. the strong affinity of water for the internal zeolite surfaces;
3. accommodation of water molecules in voids containing cations;
4. ease of regeneration;
5. long useful life (natural gas drying towers have a five-year lifetime).

**Gas Purification.** There are many and varied examples using both natural and synthetic zeolites. The natural zeolites are likely to be chabazite, clinoptilolite, or mordenite. The latter two are useful for dealing with acid gas streams.

A common purification is the use of 4A to remove CO<sub>2</sub> from natural gas as well as sweetening the gas, that is, removing H<sub>2</sub>S and nitrogen products. Zeolite 13X (synthetic faujasite containing only Na cations) also is used to remove undesirable larger molecules that contain S and N atoms from natural gas. In 2002, Engelhard introduced 'Molecular Gate' for the separation of both CO<sub>2</sub> and N<sub>2</sub> from natural gas using pressure swing applications (PSA). This material is one of the recently discovered titanium silicates (ETS-4). Already two plants in the USA are using this technology to removed unwanted gases from natural gas. Clearly, natural gas treatment plants link purification with drying and regeneration processes.

**Gas Separation.** The best-known process is the use of 5A to separate *n*- from *i*-alkanes. This is the basis of several commercial processes (e.g. Union Carbide Isosiv, and Exxon Ensorb). Their purpose is to provide feedstocks for the detergent and chemical industry. Currently there is considerable interest in using zeolites in PSA, especially in the enrichment of gases from the air. Oxygen production to hospitals is an example of this, both in the provision of oxygen lines and in portable units for individual use or in field hospitals as in the Gulf War. Again, zeolite A is widely used but clinoptilolite, mordenite, and chabazite are important PSA substrates, for example, the separation of methane and

nitrogen mixtures using clinoptilolite.<sup>44</sup> Earlier separations of this sort on zeolites were cryogenic in nature.

Finally, synthetic zeolites have long been used in gas–solid chromatography for permanent gas and hydrocarbon analyses. Some modern GC capillaries are coated with zeolites.

**Liquid Phase Separation.** UOP have pioneered several small-scale processes to fractionate mixtures of liquids. The Parex process was introduced in 1971 and by 2001 71 units were running commercially. The MX-Sorbex process was introduced in 1998 and so far 5 units have been commercialized. Very recently,<sup>45</sup> in 2001, UOP introduced a new Sorbex process, MaxEne, to increase the ethylene yield from Naphtha Crackers. Examples of these are listed in Table 30.

Only the Molex process depends upon molecular size, whereas the others function on the basis of a liquid chromatographic fractionation. Quite recent work<sup>46</sup> shows that high-silica zeolites (synthetic) make good high performance liquid chromatographic (HPLC) media. The mechanisms whereby these chromatographic separations are achieved await elucidation but it seems that both internal and external surface attractions are important, as are zeolite structures and the nature of the cation present. Silica analogs of zeolite structures are hydrophobic and so offer the possibility to separate organic molecules from aqueous environments.

**Carriers.** The encapsulation of molecules into zeolite voids has been used to handle unpleasant chemicals, such as vulcanizing agents, and to carry CO<sub>2</sub> in carbonated drinks. Other prospective uses are to store and transport methane and hydrogen.

## 5.5 Zeolites as Catalysts

### 5.5.1 Background

Some 40 years ago it was discovered that synthetic faujasites could act as effective isomerization and cracking catalysts. The latter advance, based on the pioneering work of

Plank and Rosinski, produced the current situation whereby essentially all the world's motor vehicle and aviation fuels are derived from crude oil by use of a zeolite catalyst. Zeolites have replaced the earlier silica/alumina and silica/clay catalysts in this area with a resulting annual savings estimated in billions of dollars.

The success has prompted an explosion of patents, journal publications, and conference proceedings, devoted to the study of the theory, mechanism, and utility of zeolites in promoting virtually any organic (and some inorganic) reaction. Rabo<sup>47</sup> has compiled a comprehensive treatise on the earlier work on zeolite catalysts, and Jacobs<sup>48</sup> has discussed their carboniogenic activity. Amongst the copious literature the reviews by Dwyer<sup>49</sup> on the evaluation of zeolites and the tailoring of the acid–base properties of zeolites, and by John *et al.*<sup>50</sup> describing the range of reactions catalyzed and their industrial relevance are recommended. This section provides an overview of current commercial use of zeolite catalysts with some indications of their mode of action and ease of modification (see also Section. 6).

### 5.5.2 Commercial Processes Using Zeolite Catalysts

Table 31 provides some details of zeolite catalyst usage. The best known is that of zeolite Y as a fluidized bed catalyst (FCC) to crack crude oil for gasoline production. The zeolite is used as a promoter and comprises up to 50% of a small composite with a clay or silica binder. As such it can remain stable throughout many cycles in the catalyst riser (at 480–520 °C), where it meets the downstream of crude oil followed by a steam blast to release the cracking products, and then a stream of air in a regenerator (590–730 °C). This regeneration process cleans the catalyst of coke and the residual oil products.

Clearly the success of the catalyst depends upon its ability to withstand these extreme conditions and this is one of the advantages of the ultrastable synthetic faujasite (USY) and ZSM-5 materials and is always a consideration in the other applications listed in Table 31. It is, however, only one of the known advantages acquired when zeolites are considered as industrial catalysts. Other benefits come from the zeolite

**Table 30** UOP sorbex processes for liquid phase separations<sup>38,42</sup>

| Process   | Separation                                                        | Zeolite                | Desorbent                                                       |

| Sarex     | Fructose from sucrose and other sugars (corn syrup feed)          | CaY                    | Aqueous systems                                                 |

properties of high internal surface area and variable pore sizes, which lead to both reactant and product selectivity via molecular sieving. This is described as shape-selectivity and is controlled by configurational diffusion, the phrase used to describe a diffusion-controlled regime in which useful catalytic reactions are encouraged by a matching of size, shape, and orientation of the product and reactant molecules to the molecular architecture of the zeolite.<sup>51</sup> An additional bonus comes from the ease with which zeolites can be modified; examples of this have been mentioned earlier, for example, ion exchange and the introduction of heteroatoms (other than Si and Al) into the zeolite framework. This latter change can be achieved by a postsynthetic modification and an interesting prospect is that of inducing ion exchange and catalytic properties into the uncharged frameworks of aluminophosphates (AlPO<sub>4</sub>) by inserting Si atoms into existing AlPO<sub>4</sub> structures. A further modification is that of salt occlusion, that is, the introduction of a salt ion pair into a zeolite cavity to attain improved thermal stability and to reduce the deleterious effects of trace elements such as Ni, Fe, and V, which occur in some crude oils.

### 5.5.3 Source of Zeolite Catalytic Activity

Broadly, zeolites have high catalytic activity because their structures can produce a higher proportion of the so-called active sites per unit surface area than competing catalysts. These sites are the traditional Brønsted sites that arise from the creation of hydroxyl groups and this can be via one of the three routes illustrated below.

1. Ammonium ion exchange (e.g. as in production of USY)

2. Polyvalent ion exchange (e.g. as in rare earth exchanged Y, ReY)

3. Direct ion exchange with mineral acid (e.g. with ZSM-5).

In all three cases the protonated zeolite, HZ, is created containing Brønsted sites, which, when heated above 550 °C, lose water to produce Lewis sites, viz.

The Lewis sites are unstable, especially in the presence of water vapor, and an annealing process stabilizes the structure. This is thought to create true Lewis sites by ejecting Al

**Table 31** Commercial processes using zeolitic materials

| Process                                       | Catalyst                                                              | Advantages in using zeolite-based catalysts                                   |

<sup>a</sup>(USY), Ultrastable synthetic zeolite Y treated to reduce aluminum content and improve thermal and hydrothermal stability (see Section. 6.1).

<sup>b</sup>LPG = liquid propane gas.

oxide/hydroxide species from the framework, viz.

This extra framework Al can be identified by MAS-NMR but is in at least two forms. It is these Al species that are thought to be the ‘super acid’ sites inducing the high zeolite surface reactivity.

Another aspect to zeolite catalytic activity, briefly mentioned earlier, is the use of ion-exchange modification to introduce elements of known catalytic propensity into the zeolite promoter. Examples of this are in Table 31. There has been a considerable amount of work devoted to the investigation of the dispersion of metal particles (e.g. Ni and Fe) on zeolite substrates to enhance specific organic reactions.

#### 5.5.4 The Future

The SAPO materials seem likely to provide novel catalysts, especially as the emphasis of zeolite usage turns to chemical intermediates and fine chemical production,<sup>50,52</sup> and processes using the B analog of ZSM-5 (boralite) and SAPO-34 have been commercialized.

Another advance seems likely through the use of zeolites as enzyme mimics.<sup>53</sup> This centers on the reactions of organometallics with zeolite internal surfaces. The best-known example is the production of a  $[\text{Co}^{\text{II}}(\text{bipyridyl})(\text{terpyridyl})]^{2+}$  complex inside the main cavity of zeolite Y that can selectively and reversibly absorb oxygen from the air. The catalytic potential of a Co phthalocyanine moiety prepared in the Y cavity has also been demonstrated.

## 6 COMMERCIALY USEFUL ZEOLITES AND THEIR WELL KNOWN USES

### 6.1 Synthetic Zeolite A (LTA)

#### 6.1.1 Cation Positions

The element of structure of this zeolite, illustrated in Figure 3, represents a convenient segment of the full unit cell of the LTA structure and should be described as its pseudounit cell (puc). Each puc has 12 sodium cations and, in the hydrated zeolite, eight occupy sites close to each of the S6R openings to the component  $\beta$ -cages (Site I), three are in sites near the centers of some of the S8R openings to the larger  $\alpha$ -cage (Site II), and the final sodium is in the center of the puc

(Site III). Each pseudo unit cell contains 27 water molecules, and 20 of these form a pentagonal dodecahedron that lines the  $\alpha$ -cage (Figure 17). This water structure is found in some water clathrates and in LTA surrounds the central Na ion with its attendant three water molecules. It is cation–water assemblages like this that are likely to be the precursors for the formation of zeolite frameworks in synthesis gels (see Section. 4.2.3).

The remaining four water molecules are in the  $\beta$ -cages. If the zeolite is dehydrated, the cations adopt other convenient crystallographic sites of minimum potential energy. This, of course, is common to all zeolites and ultimate sitings depend upon the Si/Al ratios and geometries of their frameworks, as well as the nature of the cation (size, charge, bonding properties); more details are available.<sup>12</sup>

In the commercial sorbents Linde Molecular Sieves 3A, 4A, and 5A, the resiting of cations on calcination tailors their effective pore sizes. In dehydrated 3A and 4A, the K and Na ions, respectively, occupy positions obstructing entry to the  $\alpha$ -cage (i.e. across the 8SR), and the cation size difference ( $\text{K} > \text{Na}$ ) changes the pore size from 3 to 4 Å. When the divalent  $\text{Ca}^{2+}$  is introduced into the large cage, there are, of course, fewer cations present ( $2\text{Na}^+ \rightleftharpoons \text{Ca}^{2+}$ ) and, upon dehydration, these occupy Site I positions, away from the S8R windows, so opening up the effective pore size to 5 Å (note that 3A and 5A are both partially exchanged forms of NaA).

One final comment is that an increase in the Si/Al ratio in the LTA synthesis encourages the production of the crystallites with chamfered edges and corners, appropriate to their detergent use.

**Figure 17** The water clathrate in the large cage of hydrated zeolite A. It is composed of 20  $\text{H}_2\text{O}$  molecules arranged in a pentagonal dodecahedron

### 6.1.2 Commercial Uses of Zeolite A

**Detergency.** NaA is now a common builder, added to solid and liquid detergents and to other household and laundry products.

**Desiccant.** The forms 3A, 4A, and 5A are in general laboratory use as drying agents for air and nitrogen lines and organic liquids. Both 3A and 4A are used worldwide to dynamically dry liquid halocarbons and hydrocarbons, especially Liquid petroleum gas LPG and natural gas. 3A is preferred for drying refinery streams containing alkenes (cracked gas), ethene, propene, and methanol, and 4A is used to dry other alcohols, benzene, and natural gas. Other industrial gas streams commonly dried by zeolite beads are oxygen, nitrogen, air, and CO<sub>2</sub> in nuclear power installations. Examples of static drying using 3A and 4A in sealed systems are widespread, for example, in sealed double-glazing units, refrigeration circuits (domestic and industrial), vehicle braking, air conditioning systems, and in heavy duty transformers filled with hydrocarbon liquids.

**Gas Separation.** 5A efficiently separates *n*- from *i*-alkanes. This is used to provide feedstocks to the detergent and chemical industries and is the basis of several commercial processes, that is, those developed by Union Carbide (Isosiv), British Petroleum BP, Shell, Texaco (TSF), Exxon (Ensorb), and VEB Leuna Werke, Bitterfeld, Germany (VEB) Germany. The latter process is called the Parex process. This should not be confused with the process of the same name developed by UOP to separate *liquid* C<sub>8</sub> hydrocarbons (see Table 30 and elsewhere), and note that UOP use 5A to separate *n*-alkanes from *i*-alkanes, naphthalenes, and aromatics in the liquid phase via their Molex process. Ambient pressure swing processes, using 5A, have been developed to produce both O<sub>2</sub> and N<sub>2</sub> from air. The nitrogen generators are used in steel-making while oxygen generators principally are used for medical purposes (for hospital oxygen lines, individual patients units, and in field hospitals), in welding, in water-oxygenating kits, and as emergency oxygen supplies in aircraft.

**Gas Purification.** The best-known purification process using 4A is that of natural gas; this involves two benefits, namely, peak-shaving whereby the calorific value of the gas is adjusted by CO<sub>2</sub> (and water) removal, and sweetening by H<sub>2</sub>S removal. The latter purification also is used in LPG treatment. Another example is the trapping of hydrocarbons in gas and vacuum circuits.

**Other Uses.** The form 5A is a traditional gas–solid chromatographic substrate for permanent gas analysis, the butane isomers, and cryogenic analyses of hydrogen isotopes. It is an additive to powders to improve flow properties and

**Figure 18** The cation sites of the faujasite (FAU) framework (see text for explanation of symbols). (Reprinted with permission from J.V. Smith, 'Molecular Sieve Zeolites-1', eds. E.M. Flanigen and L.B. Sand, *ACS Symp. Ser.*, 1971, **101**, 173. © 1971 American Chemical Society)

to dry them (including food products) and an encapsulant for CO<sub>2</sub> in carbonated drinks.

## 6.2 Synthetic Faujasites: Zeolites X and Y (FAU)

### 6.2.1 Cation Positions

Zeolites X and Y are isostructural with the natural mineral faujasite. They differ in the amount of Al occupying tetrahedral sites such that the Si/Al ratio of X is in the range 1–1.4 (but commonly 1) whilst that of Y can vary, according to synthesis conditions, up to Si/Al = 3. The cation sites available are shown in Figure 18, which represents an element of the full structure illustrated in Figure 11. The as-synthesized cation form is sodium. The cation sites can be listed as Site I in a D6R (hexagonal prism), Site I' close to the D6R in the sodalite ( $\beta$ ) cages, Site II' in the sodalite cage near the S6R entrances to the large  $\alpha$ -cage, II is in the large cages near the S6R entrances. U is at the centre of the sodalite cages and other sites (e.g. IV and V) are in less well-defined sites in the large cage.

The sites adopted by cations in these structures are complex and will not be considered here but, broadly, an increase in Si/Al (decrease in framework charge) depopulates Sites I and I' in the hydrated zeolites in favor of positions in the large cage. Removal of water causes an increase in population of the Sites I and I' regardless of framework charge. Details of individual cation sitings in ion-exchanged forms of X and Y are available,<sup>12</sup> with water molecule positions, where known.

Early references describe the Na and Ca exchanged forms of X as 13X and 10X, respectively. The figures were meant to imply their respective pore sizes, over assessments of the restriction offered by the 12SR window entry to the main cavity, which has the crystallographic dimension of 7.4 Å.

The Y framework is more stable than the X, to both thermal and hydrothermal treatments, so methods were developed to dealuminate the FAU framework to attain the improved stabilities needed for catalytic use, especially under the extreme fluidized bed conditions applied in cracking crude oil (see Section. 5.5.2). The end product is known as ultrastable Y (USY) and can be made by one of four ways: (a) acid treatment, (b) high-temperature steam treatment of the ammonium exchanged form of Y ( $\text{NH}_4\text{Y}$ ), perhaps followed by acid treatment, (c) reaction of  $\text{NH}_4\text{Y}$  with an aqueous solution of  $(\text{NH}_4)_2\text{SiF}_6$ , and (d) reaction of  $\text{NaY}$  with gaseous  $\text{SiCl}_4$ .

The last treatment is the best method of retaining the excellent crystallinity and high hydrophobicity ( $\text{Si}/\text{Al} > 25$ ) synonymous with a good fluidized cracking catalyst (FCC).

### 6.2.2 Commercial Uses of Zeolites X and Y

**Detergency.** Zeolite X has been included in some builder compositions because it has a better selectivity for  $\text{Mg}^{2+}$  than does zeolite A.

**Gas Separation and Purification.** Zeolite X has been used for many hydrocarbon separations and to trap molecules containing S and N from industrial gases. It is used to dry and purify  $\text{SF}_6$  in high-voltage switching apparatus and in oxygen-generating emergency supplies in fighter aircraft. It finds use in double-glazing units to scavenge residual solvents from the sealants used and to pick up iodine species from gaseous effluents from nuclear installations (as AgX).

**Liquid Separation.** Zeolites X and Y, in various ion-exchanged forms, are the substrates used in the processes developed by UOP for separating liquid mixtures (see Table 30). The hydrophobic nature of Y and its modified forms are used to scavenge organic molecules from aqueous environments (e.g. halohydrocarbons).

**Catalysis.** Various forms of zeolite Y find uses in industrial catalytic processes. These have already been listed in Table 31 and account for the second highest annual tonnage use of synthetic zeolites (approx 60 000 metric tonnes). This continues to increase as zeolite catalysts aid the shift to unleaded gasoline and to the use of cheaper feedstocks.

## 6.3 Synthetic Zeolite ZSM-5 (MFI)

### 6.3.1 Structure and Cation Positions

The structure of this high-silica species can be regarded as an arrangement of layers created by linking the 5–1 SBU (see Figure 2), as shown in Figure 19. The full three-dimensional framework can be regarded as a series of channels circumscribed by the 10SR seen in Figure 19. The spatial arrangement of these channels is shown in Figure 20 together with those in ZSM-11 (MEL). The cation positions have not yet been defined except that they behave as if they are occupying two distinct crystallographic sites.

**Figure 19** Sheet projection for ZSM-5 (MFI) structure showing 12SR and 8SR openings

**Figure 20** Channel arrangements in ZSM-5 (MFI) and ZSM-11 (MEL). (Ref. 40. Reproduced by permission of Society of the Chemical Industry)

### 6.3.2 Commercial Uses of ZSM-5

The hydrophobic character of the high-silica MFI framework lends itself to the separation of polar and nonpolar molecules. There are many patents claiming this use but no details of commercial processes have appeared in the literature. ZSM-5 is used as a cocatalyst in FCC compositions. This makes use of its shape-selective properties to improve the octane quality of gasoline. It has been used with both Rare-earth exchanged synthetic zeolite Y (REY) and USY. It is also an effective catalyst for the conversion of methanol to higher carbon-number molecules. This is the basis of the methanol to alkenes (MTO) and methanol to gasoline (MTG) processes developed by Mobil. This discovery offers the prospect of conversion of the methane component of natural gas to synthesis gas (carbon monoxide and hydrogen) and then to methanol and gasoline. Dimethyl ether, an important industrial intermediate, can also be obtained from these reactions.

Gallium loaded ZSM-5 is the catalyst used in the Cyclar process (UOP/BP) whereby LPG (largely propane and butane) is converted to high-octane fuels and benzene/toluene/xylene (BTX) as petrochemicals.

ZSM-5 catalyzes alkene oligomerization, using its shape-selective ability, and both Mobil and Shell (methanol to gasoline and distillates (MOGD) and polygasoline and kerosene (SPGK)) use a ZSM-5 catalyst for this purpose. The production of ethylbenzene from benzene and ethylene is catalyzed by ZSM-5 in the Mobil/Badger process. Mobil also have improved the production of benzene and xylene from toluene disproportionation using ZSM-5.

Finally, ZSM-5 is used to dewax gas oils and lubricating base oils, and to produce low-temperature diesel fuel. In all these cases, the processes catalytically remove long-chain waxy *n*-alkanes, which otherwise crystallize out at low temperatures and cause increased viscosity.

## 6.4 Mordenite (MOR)

### 6.4.1 Structure and Cation Positions

The structure of mordenite contains two channels (Figure 4), one restricted by a 12SR and one by an 8SR. Eight cations and water sites have been located, with the most occupied being at the centers of the 8SRs, adjacent to the 5SR units, which link the 12SR channels, and near to 54Rs, which link adjacent five-membered rings around the smaller channel.

Divalent ions ( $\text{Ca}^{2+}$ ,  $\text{Ba}^{2+}$ ) occupy sites in the larger channels so that, on dehydration, molecular sieving is controlled by the dimensions of the smaller channel ( $2.6 \times 5.7 \text{ \AA}$ ); when monovalent ions are introduced they lie in the small channels so that molecular sieving is controlled by the 12SR (dimension  $6.5 \times 7.0 \text{ \AA}$ ).

Early sorption experiments were carried out on natural mordenites, which behaved as small-pore sorbents (i.e. had effective pore sizes of  $<4 \text{ \AA}$ ). Synthetic mordenite behaves as a large-pore material, displaying an effective pore size closer to that expected from a 12SR opening. Later work was able to synthesize both large (LP) and small (SP) ported mordenites, and discussion has taken place over a number of years concerning the reasons for the differences between these materials. The apparent channel restrictions in SP mordenite can be ascribed to the presence of extraneous material or to the presence of stacking faults. The fact that the channels in mordenite can be enlarged by acid leaching favours the channel blockage concept. Synthetic LP mordenites have been marketed by the Norton company as Zeolon 100, 200, and 900, and the product that is available as AW300 (AW = acid washed) is also likely to be a mordenite.

### 6.4.2 Commercial Uses of Mordenite

The relatively high Si/Al content of mordenite confers on it a certain acid stability that enables it to be used to remove water from acid gas streams such as reformer recycle hydrogen, reformer catalyst regeneration gas, HCl,  $\text{Cl}_2$ , and chlorinated hydrocarbons. It can also be used to treat off-gas for removal of oxides of sulfur and nitrogen ( $\text{SO}_x$  and  $\text{NO}_x$ ). Mordenite's ion-exchange selectivity for Cs has been used to remove Cs radioisotopes from nuclear waste (Zeolon 900) and it is used in Japan on a plant scale to separate gases from the air.

LP mordenite doped with platinum is the catalyst used in the Shell Hysomer process for alkane hydroisomerization; this can be linked to the Isosiv separation process whereby *i*-/*n*-alkanes are separated on LTA zeolite. This link is the basis of the joint Shell/UOP Total Isomerization Process (TIP). Similar catalysts have been employed to hydrocrack (i.e. dewax) diesel fuels. There have also been reports of commercial use of mordenite to catalyze methanol amination with ammonia, to produce dimethylamine.

## 6.5 Chabazite (CHA)

### 6.5.1 Cation Positions

11 cation/water sites have been identified in the chabazite framework. In the hydrated mineral, the bulk of the cations are present as fully hydrated species in the large cavity with less than one  $\text{Ca}^{2+}$  per cage being in the D6R sites. On dehydration, the cation population of the D6R site increases ( $\approx 2$ ) and the other ions adopt two other sites, one just outside the six-ring entrance to the D6R and the other near four rings that connect adjacent D6Rs (see framework in Figure 6). The natural mineral (with erionite) has been marketed by Norton as Zeolon 500 and by other suppliers as AW500. Synthetic chabazite can be obtained from custom synthesis.

### 6.5.2 Commercial Uses of Chabazite

Chabazite has found a wide variety of occasional uses as a cheap desiccant and molecular sieve and as a selective ion exchanger in the nuclear industry. Current interest is in its use as a selective sorbent (in Li form for instance) in PSA and related applications.

## 6.6 Clinoptilolite (HEU)

### 6.6.1 Structure and Cation Positions

The clinoptilolite (heulandite) structure is that of an assemblage of 4-4-1 SBUs to create a layer-like array. The layers are joined to create two channels, both composed of 10SRs parallel to the crystallographic *c*-axis, and one 8SR limited channel parallel to the *a*-axis.

In clinoptilolites rich in alkali metal ions (Na/K), and in the hydrated state, two cations have specific sites in the main channels, one is in the smaller channels, and the final one lies near the center at an S8R.

### 6.6.2 Commercial Uses of Clinoptilolite

Like chabazite, clinoptilolite has been used as a cheap desiccant and molecular sieve. As noted earlier, its selectivity for Cs has led to its use in aqueous nuclear waste treatment and its ability to remove  $\text{NH}_4^+$  from water has been used on a plant scale (see Section. 5.3.2). An extensive literature describes its use in horticulture and agriculture as an amendment to soils and composts. Similarly, the benefits of its addition to animal feeds is well documented. These uses have been reviewed<sup>40</sup> and three conference reports also can be recommended for further details.<sup>54–56</sup>

## Glossary

*Chimeric (hybrid) protein:* a nonnatural protein created when homologous regions of two homologous proteins are exchanged

*Gag knuckle:* this fold is composed of short (~20 amino acids) Cys<sub>2</sub>His<sub>2</sub> zinc fingers from retroviral gag proteins

*Motif:* a primary, secondary, or tertiary structural domain

*Palindromic DNA-binding site:* a DNA sequence that contains one inverted repeat composed of two half-sites of nucleotides

*Zinc Knuckle:* this fold group is composed of two short  $\beta$ -strands connected by a turn followed by a short helix or a loop, and it also may possess a unique turn with the consensus sequence CPXCG at either termini

## Abbreviations

DBD = DNA-binding domain; HRE = Hormone response element; LIM = Lin11, Isl1, and Mec3 (abbreviations for the genes in which the LIM domain was originally discovered); MT = Metallothionein; NCP = Nucleocapsid protein; PHD = Plant homeodomain; RING = Really interesting new gene; TFIIIA = Transcription factor IIIA; activator of transcription by RNA polymerase III; zf = Zinc finger.

## 1 INTRODUCTION

The local folding of small globular domains within gene regulatory proteins is required for sequence-specific

DNA binding, an event that underlies gene expression in all kingdoms of life.<sup>1</sup> The formation of zinc-ligand coordination bonds provides the major driving force for the folding of these mini domains that lack an appreciable hydrophobic core.<sup>2</sup> Over the last two decades, an explosion in our knowledge of the diverse roles that the essential trace element zinc plays in DNA metabolism, chromatin remodeling, transcriptional regulation, nucleic acid packaging, and ribosome biogenesis has taken place.<sup>3–7</sup> Fueling this explosion is the structural characterization of zinc-containing nucleic acid-binding proteins at atomic resolution by X-ray crystallography and NMR spectroscopy. This chapter will survey these structural findings and develop unifying concepts that have emerged from these studies.

Zinc is found in all human body tissues with 30 to 40% found in the nucleus, 50% in the cytosol, and the remainder found in organelles, vesicles, and the cell membrane.<sup>8</sup> Zinc plays critical roles in the reduction of common infections, helps in the prevention of stunting growth, and supports neurobehavioral development among other attributes (see *Nutritional Aspects of Metals & Trace Elements*).<sup>9</sup> Zinc is an essential trace element in all organisms, and the unique combination of structural and thermodynamic properties of zinc make it ideally suited for a diverse array of biological roles. These properties include its ready availability, Lewis acidity, high concentration of charge (atomic radius of 0.65 Å), lack of redox reactivity and stable oxidation state (2+). Zn(II) is a  $d^{10}$  transition metal ion that forms metal complexes of high thermodynamic stability that are often characterized by facile ligand exchange (see *Zinc: Inorganic & Coordination Chemistry*).<sup>5</sup>

Zinc binds nearly exclusively to three types of amino acid side chains in proteins. These are cysteines, histidines, and carboxylates (Asp and Glu) with thiolate sulfurs and imidazole nitrogens by far the most common donor atoms. Zinc sites in proteins adopt a variety of coordination structures that differ in the number of ligands bound (coordination number), the type of ligands, metal-ligand bond lengths, dihedral ligand-metal-ligand bond angles, and, in some cases, second-shell interactions.<sup>5</sup> The Metalloprotein Database and Browser hosted by The Scripps Research Institute (<http://metallo.scripps.edu/>) reveals that among the approximately 3100 structurally characterized zinc coordination sites deposited in the Protein Data Bank (<http://www.rcsb.org/pdb>), the most prominent coordination number is four (1726), and the most common liganding pattern tetrathiolate (484), with tetrahedral or distorted tetrahedral coordination geometries by far the most prevalent for zinc sites classified as of April 2004.<sup>10</sup>

Zinc complexes in proteins perform structural, catalytic, and regulatory functions. Structural zinc sites typically adopt tetrahedral or distorted tetrahedral coordination geometries formed by four protein-derived ligands with no bound water molecules. Cysteines and histidines are by far the preferred ligands in such sites (e.g. zinc fingers; see Section 2).<sup>11</sup>

Catalytic and regulatory Zn(II) sites utilize the same amino acid ligands as structural sites, but include a greater percentage of carboxylate ligands derived from aspartate and glutamate, as well as solvent molecules ( $\text{H}_2\text{O}$ ), which are almost always found in catalytic sites in enzymes (e.g. carbonic anhydrase) (see **Zinc Enzymes**).<sup>11</sup> Cocatalytic sites, defined as catalytic metal sites that coordinate two metal ions via a bridging ligand(s) (e.g. phosphotriesterase), are formed by ligand sets similar to those found in catalytic sites, except that cysteine residues that typify structural zinc cluster sites (e.g. metallothioneins) (see **Metallothioneins**) are never found as a bridging ligand in metalloenzymes (see **Zinc Enzymes**).<sup>11</sup>

Structural zinc ions stabilize protein tertiary structure, protein–protein, and protein–nucleic acid interfaces. The zinc coordination bonds induce thermal stability and conformational rigidity to these important domains of proteins much like disulfide bonds do in oxidizing environments. In the absence of zinc, these protein domains are unfolded, exist in a predominantly random coil conformation, and are presumably subjected to rapid degradation and clearance by the cell. The most striking and seminal illustration of how ‘structural zinc’ stabilizes tertiary structure formation in DNA-binding proteins is in zinc finger (zf) proteins.<sup>12</sup> Classical  $\text{C}_2\text{H}_2$  ( $\text{Cys}_2\text{His}_2$ ) zinc finger domains, which mainly include DNA-binding proteins (they also mediate protein–RNA, protein–protein, and protein–lipid interactions) are small ( $\sim 30$  amino acid residues) domains that fold around one or more zinc ions, and are nearly exclusively found in eukaryotic organisms (see Sections 2.1–2.2).<sup>13,14</sup>

The number and complexity of structurally characterized zinc fingers has increased dramatically over the last ten years. In order to understand the seemingly endless collection of known zinc finger structures, a classification scheme was devised that combines all structures of functionally diverse proteins into well-defined fold groups, each of which is discussed here (see Section 2). Recent findings reveal that canonical  $\text{C}_2\text{H}_2$  zinc finger domains in transcriptional regulatory proteins in eukaryotes are not exclusively involved in structural stability but have also been implicated in regulating the concentration of bioavailable zinc in cells (see Section 3.5).<sup>15,16</sup>

Suboptimal or toxic (above normal physiological levels) concentrations of intracellular zinc have adverse effects on many aspects of cellular metabolism (see **Metalloregulation; Metal Ion Toxicity**). Zinc is now known to function at the level of transcription by binding directly to regulatory proteins, that is, metal sensor proteins that repress, derepress, or activate the transcription of genes that encode metal transporters (importers/exporters) and/or metal chelators. This helps cells maintain homeostasis (see **Metallochaperones & Metal Ion Homeostasis**), or an optimal steady-state concentration of zinc within the cytosol and other intracellular organelles.<sup>3,17</sup> Zinc sensor proteins and the determinants of their coordination chelates (number of ligands, types of ligands, and coordination geometry) are discussed as important factors that determine

metal selectivity (zinc vs. other metal ions) in these families of related sensor proteins (see Section 3).

## 2 ZINC-CONTAINING TRANSCRIPTION FACTORS: STRUCTURAL ZINC SITES

### 2.1 The Zinc Finger Story

Structurally distinct ‘zinc finger’ (zf) protein classes have emerged over the past two decades where the sole common feature is that each employs multiple cysteine and/or histidine residues to coordinate tetrahedrally a Zn(II) ion in order to stabilize their folds.<sup>13,18</sup> Zinc finger proteins thus defined comprise  $\approx 3\%$  of the proteins encoded by the human genome making them, by far, the most common proteins in eukaryotes.<sup>13</sup> A recent analysis of the mouse transcriptome identifies 46 distinct conserved zf protein families that constitute 7.5% of the nonredundant full-length protein sequences in that organism.<sup>19</sup> The structure and properties of DNA-binding zinc fingers, particularly the classical  $\text{C}_2\text{H}_2$  zfs (see Section 2.2 below) have been studied extensively and recently reviewed as to their structural properties and efforts at design, and myriad of biological functions including transcriptional activation and repression, DNA replication and repair, translation, programmed cell death, and metalloregulation.<sup>14,18,20–23</sup>

Zinc finger proteins have recently been classified into eight distinct structural groups distinguished by their tertiary structural folds around the zinc coordination complex and the spatial arrangement of secondary structural elements that contribute zinc ligands.<sup>12</sup> Table 1 lists representative members from each of six of these eight structural classes that are known to interact directly with nucleic acids. These are discussed in turn.

The first zinc finger domain discovered contained  $\text{C}_2\text{H}_2$  motifs found originally in nine tandemly arranged  $\sim 30$  amino acid residue repeats in the *Xenopus laevis* RNA polymerase III basal transcription factor IIIA (TFIIIA).<sup>24</sup> In 1985, it was proposed that in the presence of zinc each of these repeats defined an independently folded mini-domain where the zinc ion was ligated tetrahedrally by two  $\text{S}^-$  (Cys) and two  $\text{N}^\epsilon$  (His) side chains and the amino acids between the second and third ligands comprised the ‘fingertip’, which would interact directly with DNA.<sup>24,25</sup> All essential features of this seminal hypothesis have since proved to be correct. Figure 1 shows the crystal structure of the six N-terminal zinc fingers of *X. laevis* TFIIIA bound with 31 bp of the 5S rRNA gene promoter.<sup>26</sup> It is now known that much of the evolutionary and functional diversity of these canonical or classical  $\text{C}_2\text{H}_2$  zinc finger proteins (Section 2.2) derives from the appendage of additional conserved domains to the zf domain to create modular proteins with new functionalities. An excellent illustration of this is the ubiquitous family

**Table 1** Classes of zinc fingers

| Classification                | Fold/Motif <sup>a</sup>                                                                                                                                                    | Example(s)                                                                            | Binding domain(s)                         | Structure                                                                                                                                                              |

<sup>a</sup>Yellow spheres represent the positions of cysteine residues, and blue spheres represent positions of histidine residues; spheres showing gradients from yellow to blue represent positions predominantly occupied by cysteines and less frequently by histidines; spheres showing gradients from blue to yellow represent positions predominantly occupied by histidines and less frequently by cysteines. Red arrows represent  $\beta$ -strands, blue cylinders represent  $\alpha$ -helices. <sup>b</sup>Interleaved zinc-binding sites in treble-clef motifs and Zn2/Cys6-like motifs are represented by green lines connecting the ligands that coordinate one zinc ion and black lines connecting ligands that ligate another zinc ion.

**Figure 1** (a) A schematic domain structural representation of transcription factor IIIA (TFIIIA) from *Xenopus laevis* (top) and the primary structure of the N-terminal zinc fingers 1 to 6 with secondary structure assignments shown above the sequence (bottom). The metal-binding amino acids are in bold. Residues that possess a burgundy-shaded number above them (-1, +2, +3, and +6, corresponding to amino acid positions relative to the start of the  $\alpha$ -helix in each  $\beta\alpha$  structure) are commonly involved in making base-specific contacts with the major groove of the DNA; (b) The X-ray crystallographic structure of the six N-terminal zinc fingers of *X. laevis* TFIIIA bound to 31 bp of the 5S rRNA gene promoter determined at a resolution of 3.1 Å, with the zinc finger region represented in green and the DNA represented in blue;<sup>26</sup> (c) The X-ray crystallographic structure of the complex of fingers 4 to 6 of TFIIIA from *X. laevis* and 61 bases of 5S RNA derived from the central region of the complete nine-finger TFIIIA-5S RNA complex. Finger 4 interacts with the 'loop E' motif, finger 5 with helix V, and finger 6 with loop A.<sup>29</sup> (d) A ribbon diagram of a single  $\beta\alpha$  C<sub>2</sub>H<sub>2</sub> zinc finger from the structure of TFIIIA. Conserved Cys and His residues donate coordination bonds to the zinc ion (yellow sphere)<sup>26</sup>

of Krüppel-associated box (KRAB) zf proteins, where the appended KRAB domain functions as a potent repressor of transcription.<sup>27,28</sup>

## 2.2 Classical Zinc Fingers (C<sub>2</sub>H<sub>2</sub>)

Each zinc finger forms a compact  $\beta\beta\alpha$  structure (see Figure 1(d)) and basic and hydrophobic amino acids on the surface of the  $\alpha$ -helix make specific contacts with the edges of the nucleotide bases in the major groove of the DNA.<sup>13,14,18</sup> Two or more C<sub>2</sub>H<sub>2</sub> zinc fingers arranged in tandem are required

to bind DNA with sequence specificity, and each finger is often separated by a conserved TGEKP linker.<sup>13,21</sup> One of the known functions of the linker is to cap the C-terminus of the preceding helix, but only in the DNA-bound conformation; in the unbound protein the linker is unstructured.<sup>21,30</sup> The classical C<sub>2</sub>H<sub>2</sub> motif actually conforms to the consensus sequence (F/Y)-X-C-X<sub>2-5</sub>-C-X<sub>3</sub>-(F/Y)-X<sub>5</sub>- $\psi$ -X<sub>2</sub>-H-X<sub>3-5</sub>-H, where X represents any amino acid and  $\psi$  is a hydrophobic residue.<sup>18</sup> A single zinc ion is tetrahedrally coordinated between two cysteines at one end of a two-stranded antiparallel  $\beta$ -sheet (a  $\beta$ -hairpin) and two histidines found along one face of a C-terminal  $\alpha$ -helix (Figure 1d).<sup>18,21</sup> The conserved hydrophobic amino acids form a mini-hydrophobic core stacked on top of the zinc coordination complex. Despite this, these fingers are essentially fully unfolded when zinc is not bound.<sup>31</sup> Therefore, the stability of these domains is largely derived from zinc coordination, which induces the proper architecture of this  $\beta\beta\alpha$  structure. The structural paradigm of zf protein recognition of DNA is exemplified by the mouse transcription factor Zif268.<sup>18</sup> The primary site-specific contacts are made in the DNA major groove by the  $\alpha$ -helix through primary hydrogen-bond interactions from helical positions -1, +3, and +6 to one strand of the DNA (Figure 1b). This is considered the sequence-specific recognition motif of DNA binding by C<sub>2</sub>H<sub>2</sub> zinc fingers.<sup>18,21</sup>

Although the C<sub>2</sub>H<sub>2</sub> zfs interact nearly exclusively with duplex DNA, there are also examples of classical C<sub>2</sub>H<sub>2</sub> zfs that have been shown to interact with complex RNA and DNA/RNA heteroduplexes and mediate protein-protein interactions. One example is the Wilms' tumor suppressor protein (WT1), which binds both DNA and RNA and is thought to be involved in mRNA maturation.<sup>21,32-34</sup> The Ikaros family of transcription factors, which are essential regulators of lymphocyte development in vertebrates, is another example of zf proteins that interact with both proteins as well as nucleic acids.<sup>13,21,35</sup> Ikaros proteins contain two clusters of zf domains, with the N-terminal four-finger domain involved in DNA binding while the C-terminal two-finger cluster facilitates protein dimerization.<sup>35</sup> Interestingly, it has recently been shown that phosphorylation of Thr residues within the TGEKP linkers in Ikaros is inhibitory to DNA binding, potentially providing another level of regulatory control.<sup>36</sup>

The crystal structure of the central three-finger domain of TFIIIA (zf4-zf5-zf6), shown previously to provide major determinants for 5S RNA recognition,<sup>37</sup> complexed with 61 nucleotides of a truncated 5S RNA molecule, provides an opportunity to compare the determinants of specific DNA versus RNA recognition (Figure 1c).<sup>29</sup> In *Xenopus* oocytes, TFIIIA and 5S RNA form a 7S ribonucleoprotein (RNP) particle that constitutes the major storage form of this important ribosomal RNA. As stated above, the mode of DNA binding is quite well elucidated for TFIIIA, but the molecular basis of recognition of RNA was not. RNA molecules possess a more irregular structure than duplex DNA with a major groove that is too deep and narrow in a standard A-form

helical conformation to be accessible to the ‘reading’ helices of zf proteins. The structure reveals that zf4 and zf5 interact with the major groove sides of the ‘loop E’ motif and helix V, respectively, with zf6 bound to the conserved ‘loop A’ motif. Strikingly, zinc fingers 4 and 5 bind to 5S RNA in a manner that is superficially similar to that of the DNA complex; this is accomplished by a significantly widened major groove in these regions of the RNA. In contrast, the spatial relationship of fingers 5 and 6 in the RNA complex differs radically from that of DNA complex (compare Figure 1b vs. Figure 1c).<sup>29</sup>

## 2.3 Zinc Fingers: Treble-clef Fingers

The treble-clef motif is the underlying structural architecture of many zinc finger protein families and constitutes the second-most abundant zinc finger domain encoded by mammalian genomes, behind classical C<sub>2</sub>H<sub>2</sub> zfs. Treble-clef zinc fingers include FYVE fingers, typically found in proteins that mediate the recruitment of proteins involved in membrane trafficking and cell signaling to phosphatidylinositol 3-phosphate-containing membranes; LIM domains, often found in adaptor proteins that interact with other proteins that enable integrin signaling within focal adhesions; nuclear hormone receptor-like fingers, hormone-dependent transcriptional activators; PHD fingers, found predominantly in chromatin regulatory proteins; and RING fingers, most commonly associated with ubiquitin protein ligases (Table 1). They are characterized by undetectable amino acid sequence similarity and an enormous diversity of biological function. Besides DNA binding, treble-clef finger proteins therefore mediate protein-RNA and protein-protein interactions in biological processes related to apoptosis, cell-cycle control and protein ubiquitination, leading to protein degradation and turnover. In most instances, treble-clef motifs are derived from large, multidomain proteins.<sup>12</sup>

Coordination of each of the zinc ions in treble-clef fingers is either via four thiolate ligands (C<sub>4</sub>), a Cys<sub>3</sub>His, or a Cys<sub>2</sub>HisCys structure. The designation of this large family of proteins derives from the fact that when the C $\alpha$  trace of a member of this class is viewed in a specific orientation, the polypeptide chain resembles a treble-clef sign found in musical notation.<sup>38</sup> The treble-clef finger consists of a  $\beta$ -hairpin (see Figure 2; containing the ‘a’ and ‘b’  $\beta$ -strands) that incorporates a zinc-ligating C-X<sub>2</sub>-C sequence, designated as a zinc knuckle, followed by a loop, and a second orthogonally positioned  $\beta$ -hairpin (containing the ‘c’ and ‘d’  $\beta$ -strands) connected to a C-terminal  $\alpha$ -helix (see Table 1 and Figure 2). A zinc knuckle is defined here as composed of two short  $\beta$ -strands connected by a turn followed by a short helix or a loop (it may also possess a unique turn with the consensus sequence CPXCG at either termini).<sup>12</sup> The last two zinc ligands (from a C-X<sub>n</sub>-C sequence) are derived from the C-terminus of  $\beta$ -strand ‘d’ and a residue from the immediately adjacent  $\alpha$ -helix.<sup>12,13,38,39</sup> This domain is stabilized by the bound zinc ion and does not have a pronounced hydrophobic

**Figure 2** Ribbon representation of treble-clef zinc finger.<sup>38</sup> The protein ribbon corresponds to the structure of the Cys2 activator-binding domain of protein kinase C.<sup>40</sup> Examination of the structures of 42 treble-clef zinc fingers reveals that structural zinc ions are bound at up to eight distinct sites (displayed as spheres numbered from 1 to 8) in this fold.  $\beta$ -Strands and  $\alpha$ -helices are labeled in lower and upper case letters, respectively. The short  $\beta$ -strands in the zinc knuckle region are shown in purple (a and b) with the zinc knuckle turn shaded red. The other two  $\beta$ -strands are colored yellow (c and d) and the  $\alpha$ -helix is colored light blue (A). Metal ion 1 occupies the canonical treble-clef zinc site, with ions roughly corresponding to 2, 3, 5 and 8 corresponding to the second ‘interleaved’ zinc site found in RING, PHD, and FYVE zinc fingers (see Table 1). Metal ions labeled 4, 6, and 7 represent three additional sites accommodated by this basic fold. (Ref. 38. Reproduced by permission of Oxford University Press)

core.<sup>38</sup> Although the basic treble-clef motif contains a single zinc-binding site (corresponding to ion 1, Figure 2), many treble-clef finger proteins incorporate a second interleaved zinc-binding site within the same basic fold (e.g. RING, PHD, and FYVE finger domains, corresponding approximately to metal ions labeled 2, 3, and 8 in Figure 2), while others (e.g. LIM proteins) contain tandemly duplicated treble-clef motifs (Table 1). Strikingly, at least four additional distinct Zn(II) chelates can be accommodated by the basic treble-clef architecture (ions labeled 4, 5, 6, and 7 in Figure 2), suggesting considerable evolutionary pressure to maintain the functionality of this biologically important fold.

### 2.3.1 Nuclear Hormone Receptor-like Zinc Fingers

This subfamily within the treble-clef class is comprised of a large group of evolutionarily related nucleic acid proteins involved in transcriptional or translational regulation. This class of proteins include ribosomal proteins (S14, L24e, and L31e), the zinc-binding domain of the DNA repair factor XPA, and recombination endonucleases (VIII and I-TevI).<sup>12,38</sup> Nuclear receptor-like fingers also include GATA-1 and nuclear hormone receptor DNA-binding domain proteins.

Mammalian nuclear receptors regulate the expression or activation of target genes from promoter sequences that contain either a palindromic or a direct repeat DNA sequence collectively termed hormone response elements (HREs). Most nuclear receptors bind to HREs as either a homodimer

of steroid hormone receptors or heterodimers containing one retinoid X receptor (RXR) subunit and one nonsteroid hormone receptor subunit. Two highly conserved 66-residue core  $\alpha$  DNA-binding domains (DBDs) from two hormone receptor protomers make up the dimer.<sup>41</sup> Specific ligands recognized by these receptor proteins bind to C-terminal regulatory domains, known as the ligand binding-domain (LBD), which is connected to the N-terminal DBD by a hinge region.<sup>41</sup> Known ligands include sex steroids, for example, estrogen, progesterone, and testosterone, glucocorticoids, mineralocorticoids, bile acids, vitamin D<sub>3</sub>, thyroid hormone, and retinoids.

The DBD of nuclear hormone receptors bind two zinc ions tetrahedrally through two conserved C<sub>4</sub> motifs. The N-terminal zinc site is a prototypical treble-clef zinc finger (Table 1) where the  $\alpha$ -helix is positioned in the major groove of the conserved DNA half-sites.<sup>13,38,41</sup> The C-terminal zinc domain stabilizes the DBD dimerization interface. The structures of the glucocorticoid receptor (GR) and estrogen receptor (ER) homodimers on their cognate HREs were the first ones reported.<sup>42,43</sup> In the last ten years, structural studies together with biochemical and genetic data, on the DBD of RXR in combination with various nuclear receptor partners, as well as studies on the monomeric complex of NGFI-B, have helped decipher the mechanisms by which members of this class of  $\alpha$  proteins selectively bind their cognate DNA targets.<sup>41,44–46</sup>

## 2.4 Zinc Fingers: Zinc-Ribbon Motif

The zinc-ribbon motif consists of two structurally similar CPXCG zinc knuckles derived from two  $\beta$ -hairpins within a three-stranded antiparallel  $\beta$ -sheet (Table 1). The tertiary structural organization of the zinc-binding site bears a striking resemblance to the Fe-binding site in the electron transfer protein rubredoxin.<sup>47</sup> Some zinc-ribbon proteins are characterized by a long C-terminal  $\beta$ -hairpin that donates the third and fourth zinc ligands, thus the name ribbon.<sup>12</sup> The zinc ribbon is unique among  $\alpha$  proteins in that it completely lacks  $\alpha$ -helical structure with all zinc-ligating residues derived from  $\beta$ -hairpins. The zinc ligation pattern is predominantly C<sub>4</sub> but some members contain C<sub>3</sub>H coordination complexes.

The zinc-ribbon motif is found in a diverse group of proteins with limited sequence similarity and includes proteins involved in transcription (e.g. Transcription Factor IIB<sup>47</sup>) and translation (the G domain of the  $\gamma$ -subunit of the heterotrimeric translation initiation factor eIF2).<sup>12,47,48</sup> In TFIIB, the surface of the ribbon domain is conserved and is essential for the recruitment of RNA polymerase II (Pol II) to the Preinitiation Complex (PIC).<sup>49</sup> The GCM (glia cell missing) transcriptional regulators make novel use of a ribbon-like zinc complex to bind to DNA in an unusual way. Here, one edge of a five-stranded antiparallel  $\beta$ -sheet inserts into the major groove. The middle three antiparallel  $\beta$ -strands of the five-stranded

sheet coordinate a zinc ion via two His and two Cys residues; this complex tethers the DNA-binding domain to a secondary distal domain that also contains a C<sub>2</sub>H<sub>2</sub>-like mixed  $\alpha/\beta$  zinc finger.

In addition, three enzymes involved in DNA replication, including DNA primases, prokaryotic DNA topoisomerase I and some hexameric DNA helicases, are also classic zinc-ribbon proteins.<sup>50</sup> In bacteriophage DNA primases, mutations of the zinc-binding residues abrogate the synthesis of RNA primers for lagging strand DNA synthesis.<sup>50</sup> Strikingly, each subunit of the mini-chromosomal maintenance (MCM) protein, a heterohexameric helicase that initiates DNA replication in *S. cerevisiae*, contains an independently folded zinc-ribbon domain that appears to stabilize the dodecameric structure (a dimer of hexamers) of this replication complex.<sup>51</sup>

## 2.5 Zinc Fingers: Gag Knuckle

Gag knuckles are comprised of a zinc knuckle (two short  $\beta$ -strands connected by a turn) connected to a short  $\alpha$ - or 3<sub>10</sub>-helix or a loop (Table 1). They conform to the consensus sequence, Cys-X<sub>2</sub>-Cys-X<sub>4–16</sub>-His-X<sub>4</sub>-Cys, originally discovered in retroviral gag-gene encoded nucleocapsid proteins.<sup>52</sup> Gag knuckles are more broadly defined by Grishin as  $\approx 15$  to 25 amino acid C<sub>2</sub>H<sub>2</sub> or C<sub>2</sub>HC modules that incorporate the zinc knuckle found in retroviral gag proteins.<sup>12</sup> The  $\beta$ -hairpin and  $\alpha$ -helix of the gag knuckle is truncated relative to classical C<sub>2</sub>H<sub>2</sub> zinc fingers, thus their designation as knuckles rather than fingers.<sup>53</sup> There are three subfamilies of gag knuckle proteins that carry out different biological functions and include retroviral nucleocapsid proteins, eukaryotic transcription factor IIA (TFIIA), and the reovirus outer capsid protein  $\sigma 3$ .

### 2.5.1 Retroviral Gag Knuckle

Retroviral nucleocapsid proteins (NCPs) are the major RNA-packaging proteins of animal retroviruses. The retroviral gag knuckle appends an N-terminal  $\beta$ -hairpin to one turn of a 3<sub>10</sub>- or  $\alpha$ -helix.<sup>12</sup> These are small ( $\sim 50$ – $100$  residues), extremely basic proteins that usually possess two conserved knuckle domains that conform to a Cys-X<sub>2</sub>-Cys-X<sub>4–16</sub>-His-X<sub>4</sub>-Cys sequence separated by a short (5–15 amino acid) linker. Retroviral gag knuckles recognize and bind to specific sequences of single-stranded RNA (ssRNA), which then allows for RNA encapsidation and replication of these viruses;<sup>12,52</sup> they also possess potent nucleic acid chaperone activity.<sup>54</sup> Gag knuckles are mostly found as two conserved domains separated by a linker of variable length and amino acid composition. This differs from the classical C<sub>2</sub>H<sub>2</sub>  $\alpha$  proteins, where tandem  $\alpha$  domains are typically repeated more than twice and contain high sequence conservation in a large subset of linkers.<sup>12</sup>

## 2.6 Zinc Fingers: TAZ2 Domain-like

Transcriptional adaptor zinc finger (TAZ) domain proteins function by mediating protein–protein interactions between the basal transcriptional machinery and transcription factors.<sup>12,21</sup> This domain folds around three tetrahedrally coordinated zinc ions and adopts a novel triangular domain structure. The TAZ2 family is one of three distinct subfamilies of TAZ domain proteins, and includes the TAZ1 and TAZ2 domains found in the ubiquitous transcriptional coactivator CREB-binding transcriptional adaptor protein (CBP).<sup>55</sup> The ligation pattern contains three duplicated HCCC-type zinc-binding sites, and each site is formed by the C-terminus of an  $\alpha$ -helix, a short loop, and the N-terminus of the next  $\alpha$ -helix (Table 1).<sup>12</sup> Other members of this class include the zinc-binding domain of DNA polymerase III  $\gamma$  subunit from *E. coli* and the N-terminal domain of HIV-1 integrase. The ligation pattern for these proteins are C<sub>4</sub> and C<sub>2</sub>H<sub>2</sub>, respectively.<sup>12</sup>

It was recently shown that the catalytic core of *E. coli* RecQ, a helicase-primase and homolog of the human BLM protein, contains a single TAZ2 domain-like helix-loop-helix zinc-binding motif.<sup>56</sup> Mutations of the human gene, BLM, cause Bloom's syndrome in humans. The ligation pattern in RecQ is C<sub>4</sub>, and the zinc-binding motif is formed by the N-terminus of an  $\alpha$ -helix, a short loop, and the N-terminus of the next  $\alpha$ -helix. The product of the potent SV40-tumor promoting oncogene, large T-antigen (LTg) also possesses a RecQ-like C<sub>2</sub>H<sub>2</sub> TAZ2 zinc domain where the first two cysteines are derived from the N-terminus of an  $\alpha$ -helix with the two histidines from the N-terminus of the next  $\alpha$ -helix.<sup>57</sup> It has been suggested that the TAZ2-like zinc domain stabilizes the biologically active, hexameric form of this replicative LTg helicase.

## 2.7 Zn2/Cys6-like Finger

These DNA-binding proteins are unique among zf proteins, in that two tetrahedrally coordinated zinc ions are ligated by six conserved cysteines, with two bridging thiolates shared between the metal ions. This motif has been dubbed a binuclear cluster, reminiscent of metallothioneins, Cys-rich intracellular zinc chelators (see *Metallothioneins*). The zinc-binding domains possess two ligands from a helix and two ligands from a loop (see Table 1).<sup>12</sup> These transcriptional regulators function as homodimers and are ubiquitous in fungi and notably absent in higher eukaryotes.<sup>58</sup> Structurally characterized binuclear cluster zf proteins include the *S. cerevisiae* transcriptional regulators Gal4, Hap1, and PUT3.<sup>58</sup>

## 2.8 Other zf Domains

A comprehensive compilation of zinc finger domains encoded by mammalian genomes (<http://www.ebi.ac.uk/>

InterPro) contains 46 conserved zinc finger domains.<sup>19</sup> As mentioned above, the combinatorial diversity of these protein families arises from the modularity of the zf domain itself, which has been repeatedly fused to other conserved domains to create new proteins with new biological functions during evolution. Of particular note are two new motifs that have been recently identified in *enzymes* involved in chromatin remodeling and gene silencing. These are histone lysine (K) methyltransferases (HKMTs; e.g. *N. crassa* DIM-5 and human SET7/9) and sirtuins, NAD<sup>+</sup>-dependent Sir2 (silent information regulator protein 2) protein (histone) deacetylases. Many HKMTs incorporate *in toto*, a Zn<sub>3</sub>-Cys<sub>9</sub> triangular zinc cluster structurally superimposable on the  $\beta$ -domain of mammalian metallothioneins (see *Metallothioneins*). Although relatively far from the active site and of unknown function, removal of zinc from this domain greatly inhibits histone methylase activity. Recent experiments suggest that a fourth C<sub>4</sub>-Zn(II) binding site is assembled near the active site upon binding of the methyl donor substrate AdoMet; formation of this chelate appears absolutely essential for catalytic activity. Sirtuins contain a structural C<sub>4</sub> zinc ribbon-like motif, where the zinc ion is coordinated via two ligands derived from a  $\beta$ -hairpin and two derived from a loop between a  $\beta$ -strand and an  $\alpha$ -helix rather than a second  $\beta$ -hairpin as in the classical zinc-ribbon motif (Section 2.4). Although far from the active site, in at least one sirtuin, *S. cerevisiae* Hst2, this zinc-binding module may well negatively regulate deacetylase activity by stabilizing assembly of a catalytically inactive homotrimeric enzyme.<sup>59</sup>

Additional proteins with novel zinc-binding domains include the SQUAMOSA promoter binding proteins (SBPs), which are plant-specific transcription factors that possess two zinc finger domains within a  $\approx 65$  residue globular domain. The N-terminal zinc finger somewhat resembles the classical  $\beta\beta\alpha$  zinc finger (Section 2.2) and is followed by a C-terminal zinc ribbon-like DNA-binding domain (Section 2.4).<sup>60</sup> The N-terminal zinc finger consists predominantly of a C<sub>3</sub>H ligation pattern while the C-terminal domain possesses an invariant C<sub>2</sub>HC ligation pattern. These novel structures also suggest new modes of DNA recognition by zinc finger proteins.<sup>60</sup> Another zf protein characterized by an unclassified fold is the  $\approx 70$  amino acid tandem zinc finger (TZF) domain of the TIS11d protein, which regulates posttranscriptional control of mRNA stability by binding to class-II AU-rich elements (AREs) in the 3' UTR of target mRNAs.<sup>61</sup> TIS11d contains two highly conserved CCCH zinc finger motifs with an invariant 18-residue linker. Although largely devoid of regular secondary structure, each CCCH zinc finger superficially resembles the retroviral Gag knuckle (Section 2.5), and contains a short  $\alpha$ -helix after the first ligating cysteine, a turn of  $3_{10}$ -helix between the second and third cysteine and another  $3_{10}$ -helix located at the interface between finger 1 and the linker.<sup>61</sup>

### 3 REGULATORY ZINC IN METALLOREGULATORY PROTEINS

Transition metal ions, including Zn(II) are essential for survival, but become toxic at high intracellular concentrations (see *Metal Ion Toxicity*). In all kingdoms of life, cells must therefore be capable of regulating the steady-state concentration or available pool of individual metal ions via the coordinate regulation of specific metal import and metal efflux or chelation systems. This metal homeostasis (see *Metallo-chaperones & Metal Ion Homeostasis*) is established by metalloregulatory proteins that ‘sense’ when the concentration or pool of a particular transition metal ion in the cytosol or an intracellular compartment becomes either deficient or exceeds critical levels required for normal cellular metabolism (see *Metalloregulation*). Through extensive biochemical, molecular genetic and more recently, whole genome sequencing efforts, a large number of known or putative metal-responsive regulator proteins have been identified, especially in eubacteria and archaeobacteria. Four distinct subfamilies of prokaryotic metal-sensing transcriptional regulators have emerged from these studies and include the MerR, ArsR (or SmtB/ArsR), DtxR and Fur families of metalloregulators. Zinc-specific metalloregulators in each family have been discovered, and in some cases extensively characterized as to the structure of the coordination chelate, how individual family members recognize or detect a specific metal ion, and how metal binding positively or negatively allosterically regulates DNA binding and transcription of the resistance or uptake operons. These aspects of metal regulation in prokaryotes, and to a lesser degree, in eukaryotes, are discussed in turn.

#### 3.1 MerR Family

The MerR family of regulators activate gene expression by distorting the operator DNA sequence and causing RNA polymerase to initiate transcription at an otherwise suboptimal promoter.<sup>62</sup> Members of this family are characterized by N-terminal winged-helix DNA-binding domains, followed by a long coiled-coil region. The C-terminal helical domain is the effector binding domain.<sup>62</sup> MerR orthologs that bind a wide range of inducers including metal ions, lipophilic drugs, nitric oxide and superoxide (induced by oxidative stress) are known. The paradigm of this family and hence where the name derives comes from the seminal studies of *merR* genes of transposons Tn501 from *P. aeruginosa* and Tn21 from *Shigella flexneri* R100 plasmid. In gram-negative systems, MerR regulates expression of the mercury resistance divergon (*merTP(C/F)AD(E)* and *merR*) from the major regulated promoter.<sup>63</sup> MerR has been shown to bind to the operator/promoter region of the *mer* operon that contains a 7-4-7 inverted repeat. MerR activates the transcription of the operon in the presence of Hg(II) and acts as a weak repressor in the absence of Hg(II).<sup>62</sup> A unifying feature of

the family of MerR is that repression and activation requires the regulator to be bound on the –35 and –10 regions of the promoter. The –35 and –10 regions are separated by a longer spacer than normal (19 bp versus 17 bp). This suggested that the promoter structure was important to the regulatory mechanism. Activation distorts the DNA at the center of the operator to realign the –35 and –10 sequence, allowing RNA polymerase to transcribe the genes upon activation.<sup>64</sup> Insertions or deletions (1 to 2 bp) in the 19-bp spacer have been shown to abolish promoter activity or increase constitutive promoter activity, respectively, indicating the 19-bp spacer is essential for regulation.<sup>62</sup>

Although the structure of MerR has not yet been solved, the X-ray crystallographic structures of BmrR and MtnR, two MerR orthologs that regulate multidrug resistance in pathogenic bacteria have been determined.<sup>65,66</sup> More recently, the crystal structures of two *E. coli*-derived metal regulators from the MerR family have been reported. These include the zinc-specific regulator ZntR (to 1.9 Å resolution) (Section 3.2.1), and CueR, a Cu(I) sensor (to 2.2 Å resolution), which regulates the expression of the efflux pump CopA and periplasmic copper oxidase CueO in response to moderate copper stress (see *Metal Ion Toxicity; Metallochaperones & Metal Ion Homeostasis*). Au(I)- and Ag(I)-liganded complexes of CueR (to 2.5 and 2.1 Å resolution, respectively) have also been determined.<sup>67</sup> The metal coordination environment of these proteins is likely essential for determining metal specificity of MerR proteins.

##### 3.1.1 *E. Coli* ZntR: A Zn(II)-dependent MerR Family Regulator

*E. coli* ZntR is mainly zinc inducible and regulates the expression of *zntA*, which encodes a Zn(II)/Cd(II)/Pb(II) ATPase. The ZntR operator is uniquely defined by a 20-bp sequence spacer between the canonical –35 and –10 regions of the promoter. ZntR exists as a dimer, binds two zinc ions per monomer (as determined by X-ray crystallography), and utilizes a MerR-like DNA distortion mechanism to activate the expression of *zntA*.<sup>67,68</sup> Strikingly, X-ray crystallography reveals a binuclear zinc site with each zinc ion bound in a tetrahedral coordination environment and an internuclear Zn–Zn distance of 3.6 Å.<sup>67</sup> One zinc ion (designated as A) is ligated by Cys114 and Cys124 of the metal-binding loop while the other zinc ion (designated as B) is ligated by Cys115 and His119 of the same metal-binding loop (Figure 3).<sup>67</sup> The two zinc ions are bridged by the oxygen atoms of a phosphate (or sulfate) anion and by Cys79' from the other protomer.

This binuclear Zn(II) coordination complex in ZntR, coupled with the bound anion, was totally unexpected since Hg–MerR requires just one trigonally coordinated Hg(II) ion that bridges the MerR dimer to effect metalloregulation of the *mer* operon.<sup>62</sup> The extent to which occupancy of one or both metal sites in each of two symmetry-related metal-binding loops in ZntR regulates transcriptional activation has yet to

**Figure 3** (a) Structure of the  $Zn_4ZntR$  dimer. The ribbon diagram shows one protomer in red and the other in green. The N-terminal ~50-residue DNA-binding domains are not present in this structure.<sup>67</sup> The long  $\alpha$ -helix is the dimerization helix while the metal-binding domain is formed by a metal-binding loop that connects the dimerization helix and two short C-terminal  $\alpha$ -helices. (b) Close-up of the metal-binding domain of ZntR with two bound zinc ions shown as yellow spheres. Four zinc-ligating residues are derived from the red protomer (C114, C115, H119, and C124), while a phosphate (or sulfate) anion and the side chain of C79' from the green protomer bridge the two zinc ions. (c) Sequence alignment of Hg(II)-specific Tn501 MerR, Zn(II)-specific *E. coli* ZntR, and Cu(I)-specific *E. coli* CueR.<sup>67</sup> Known metal-binding residues are colored red and are boxed. Secondary structure elements are represented above the sequence:  $\beta$  strands, horizontal arrows;  $\alpha$ -helices, zig-zag arrows

be firmly established, although substitution of all five protein-derived zinc ligands reduces or abrogates the Zn(II) response in vivo.<sup>69</sup> Interestingly, inspection of the ZntR structure and sequence alignment of known ZntRs suggests that a  $C_3H(D)$  mononuclear, tetrahedral Zn(II) complex involving Cys114, His(Asp)119, Cys124 and Cys79' could also be readily accommodated by ZntR. Interestingly, His29 and His53 are also required for metalloregulation, although these additional residues likely play a role in mediating DNA distortion by Zn(II)-ZntR.<sup>69</sup> Three of the four metal-binding cysteines in ZntR (Cys79', Cys114, and Cys124) are conserved in Hg-sensing MerRs, and likely constitute the donor atoms to the subunit-bridging *tris*-thiolato Hg(II) complex. In Cu(I)-CueR, cysteines analogous to Cys114 and Cys124 form a linear S-Cu-S regulatory complex. Only in known zinc-sensing ZntRs are His29, His53 and His119 invariant or conserved. Hence, the metal selectivity of MerR family members appears to derive from differences in coordination number and type of metal ligands utilized by different proteins (see Figure 3), a finding exactly analogous to that previously demonstrated for two members of the ArsR/SmtB family, a zinc-sensing *S. aureus* CzrA versus the nickel-sensing NmtR (Section 3.2).<sup>70</sup>

As a further test of the inducer specificity of the metal-binding domains in MerR proteins, a chimeric protein has been characterized in which the N-terminal winged-helix DNA-binding domain (44 residues) of Tn501 MerR was fused to the C-terminal 103 amino acids of ZntR and transcriptional activation measured from a *mer* operator/promoter that

contained a 20-bp -10/-35 spacer uniquely characteristic of the *zntA* promoter rather than the wild-type 19-bp spacer in the *mer* operon.<sup>71</sup> This hybrid protein responded to Zn(II), but not Hg(II), consistent with the hypothesis that the C-terminal metal-binding domain of MerR proteins plays a major role in metal selectivity and adjustment of the appropriate degree of DNA distortion required by various operator-promoters.<sup>62</sup>

### 3.2 SmtB/ArsR Family: *S. Aureus* CzrA and *Synechococcus* SmtB

The SmtB/ArsR family consists of homodimeric 'winged' helix-turn-helix (HTH) transcriptional repressors that are specifically bound to their operator/promoter (O/P) DNA-binding sites in the metal-free apo state. Metal binding allosterically negatively regulates DNA binding and de-represses transcription.<sup>72</sup> Most of the O/P sequences of this family contain one or two imperfect 12-2-12 inverted repeats but little is known at the molecular level of how apo-repressor binds to these sites. The name of this family is derived from its two founding members, ArsR from *E. coli* and *Synechococcus* PCC 7942 SmtB. ArsR is an arsenic/antimony-responsive repressor of the *ars* operon that encodes an arsenate reductase, as well as proteins required for metal export.<sup>72-74</sup> SmtB functions as a zinc-responsive repressor that represses transcription of a divergently transcribed operon containing both the *smtA* gene (encodes a class-II metallothionein) and the *smtB* gene (Figure 4).<sup>72,75,76</sup>

**Figure 4** (a) A ribbon representation of the X-ray crystallographic structure of  $\text{Zn}_2$  SmtB is shown with one protomer in green and the other in red.<sup>77</sup> Residues known to ligate the  $\alpha 5$   $\text{Zn(II)}$  ions are shown. (b) Multiple sequence alignment of *Synechococcus* SmtB, *S. aureus* CzrA, and *S. aureus* pI258 CadC. Known metal-binding residues are boxed.<sup>72</sup> Residues shown to be involved in negatively allosterically regulating DNA binding are colored red. Blue residues are ligands to a second  $\text{Zn(II)}$  or  $\text{Cd(II)}$  but are *not* involved in metal sensing.  $\alpha 3\text{N}$  amino acids are the boxed and red cysteines in CadC. Secondary structure elements are as defined in Figure 3

Ten years of molecular genetic, biochemical, biophysical, and structural studies reveal that this family of metal-sensing transcriptional repressors generally possesses two well-characterized metal-binding sites (for a recent review see Busenlehner *et al.*<sup>68</sup>). They are termed the  $\alpha 3\text{N}$  site and the  $\alpha 5$  site. The  $\alpha 3\text{N}$  site is composed of cysteine residues from the N-terminal portion of the protein and a highly conserved ELCVCD motif in  $\alpha 3$  (Figure 4), initially termed the ‘metal-binding box’.<sup>72</sup> The  $\alpha 5$  site is composed of histidines and carboxylate residues, and is found in the C-terminal portion of the protein. Not all members of this family contain both metal-binding sites. Some possess  $\alpha 3\text{N}$  only and others  $\alpha 5$  only, some have both sites, and a few have neither site (these proteins appear to possess a new, as yet to be characterized site).<sup>72,78</sup> The  $\alpha 5$  site interacts preferably with smaller divalent metal ions, for example,  $\text{Zn(II)}$ ,  $\text{Co(II)}$ , and  $\text{Ni(II)}$ , while the  $\alpha 3\text{N}$  site preferentially binds larger thiophilic metal ions such as  $\text{Cd(II)}$ ,  $\text{Pb(II)}$ , and  $\text{Bi(III)}$ . SmtB/ArsR proteins that possess both metal-binding sites have been shown to utilize only one site for regulation, not both sites. What factors determine which site is functional in a protein that possesses both sites is

still unclear, but it is known that this selectivity of the allosteric response requires determinants outside of the primary metal ligands.<sup>70,77,79</sup>

### 3.2.1 SmtB/CzrA

*Staphylococcus aureus* CzrA is a  $\text{Zn(II)/Co(II)}$  sensing repressor. Like SmtB, CzrA metalloregulates DNA-binding through zinc binding to the  $\alpha 5$  site, which results in a quaternary structural conformational change that stabilizes a low affinity DNA-binding conformation.<sup>70,77</sup> Structural studies performed on apo- and  $\text{Zn(II)}$ -forms of CzrA and SmtB reveal that the  $\alpha 5$  metal-binding site is formed by a pair of ligands derived from the  $\alpha 5$  helix of one protomer, D84 (D104 in SmtB) and H86 (H106), and two derived from the  $\alpha 5$  helix of the other protomer, H97 (H117) and H100 (E120) (Figure 4).<sup>77</sup> The crystal structure of the  $\text{Zn(II)}$ -bound form of SmtB reveals an intersubunit hydrogen-bonding network that appears to link the metal-binding site ( $\alpha 5$ ) to the putative DNA-binding helix ( $\alpha \text{R}$ ). The  $\text{N}\epsilon 2$  atom of His117 (the

nonliganding nitrogen of this histidine) is within hydrogen-bonding distance to the backbone carbonyl of R87 in the Zn(II)-ligated state (2.67 Å N-O), while in the apo-protein it is not (3.6 Å N-O distance). The residue adjacent to R87 is a conserved L88 that then donates a backbone hydrogen bond via its amide proton to the backbone carbonyl of a conserved L83 in the DNA recognition helix ( $\alpha$ R) (Figure 4). Detailed hydrogen-deuterium exchange studies carried out with *S. aureus* CzxR by NMR methods are consistent with the formation of this hydrogen-bonding network in solution as well, with zinc binding to the  $\alpha$ 5 sites dramatically dampening internal motion throughout the dimer.<sup>77</sup> This work provides the first clear evidence of how metal binding allosterically regulates DNA binding in a prokaryotic metalloregulator at the atomic level.

### 3.3 DtxR Family: TroR

The DtxR family of regulators is named after its founding member DtxR from *Corynebacterium diphtheria*. DtxR and a homolog found in *M. tuberculosis*, IdeR, function as Fe(II)-dependent repressors that bind to a hyphenated palindromic sequence as a dimer.<sup>80</sup> DtxR negatively regulates genes required for iron acquisition, and expression of a major virulence factor, diphtheria toxin, in response to its corepressor iron. DtxR contains an N-terminal winged-helix ( $\alpha\alpha\beta\beta\alpha$ ) DNA-binding domain followed by a helical dimerization domain; some DtxRs also contain a C-terminal Src homology 3 (SH3)-like domain that is rare in bacterial proteins.<sup>81</sup> At least 18 crystallographic structures of *C. diphtheria* DtxR and *M. tuberculosis* IdeR have been reported with a variety of divalent metal ions bound, in the presence and absence of DNA. While the coordination structures and functional importance of these bound metal ions is controversial, two distinct metal sites in DtxR/IdeR, termed site 1 and site 2, emerge from these studies. Metal site 1 adopts a distorted octahedral coordination geometry and is coordinated by three residues derived from the  $\alpha$ 4 (H79, E83) and  $\alpha$ 5 (H98) helices (Figure 5c), and two residues contributed by the C-terminal SH3 domain (E170 and Q173). Metal site 2 is the putative metalloregulatory site, and adopts a distorted pentacoordinate geometry formed by three closely spaced and invariant residues in the  $\alpha$ 5 helix (C102, E105, and H106) as well as M10 from helix  $\alpha$ 1 (Figure 5c).<sup>81</sup>

DtxR (IdeR) orthologs have recently been discovered that are involved in the regulation of genes that encode metal transporters apparently specific for other divalent metal ions, including Mn(II) and perhaps Zn(II). These include *Bacillus subtilis* MntR, highly specific for Mn(II), and *Treponema pallidum* TroR. *B. subtilis* MntR regulates the expression of two manganese transporters, the Nramp-type transporter MntH under high Mn(II) and the ABC-type transporter MntABCD under low Mn(II) conditions.<sup>82,83</sup> In high manganese, Mn(II)-MntR functions as a repressor by binding to operators upstream of the coding regions of both *mntH* and *mntABCD* operons.

MntR is selective for manganese while DtxR is activated to bind DNA by various divalent metals including manganese *in vitro*.

Strikingly, the high-resolution crystallographic structure of Mn(II)-bound MntR (to 1.75 Å resolution) reveals a binuclear Mn(II) center, with the two Mn(II) ions bridged by two glutamates, E102 and E11, the latter unique to MntR, and a solvent molecule (Figure 5a).<sup>83</sup> The other ligands to the site A Mn(II) ion are H77 and E99 (C102 in DtxR) and two water molecules, creating a distorted octahedral coordination geometry.<sup>83</sup> Mn<sub>B</sub> also adopts an octahedral geometry and is ligated by D8, which is M10 in Fe(II)-sensing DtxR, H103, and two solvent molecules, in addition to the bridging ligands E11 and E102.<sup>83</sup> Mn<sub>B</sub> is roughly positioned in the same place as a Co(II) ion bound to metal site 1 in IdeR. In an effort to understand the molecular basis of metal ion discrimination between DtxR/IdeR and MntR, a D8M substitution mutant of MntR was functionally and structurally characterized. D8M MntR shows relaxed specificity for Mn(II) and is activated by both Fe(II) and Mn(II) *in vivo*.<sup>84</sup> The high-resolution crystallographic structure of D8M MntR (to 1.6 Å resolution) reveals why (Figure 5b): D8M MntR retains just one of the two Mn(II) ions and is coordinated by E11, H77, E102, and a solvent molecule (the introduced M8 is *not* ligated to the metal) in a distorted trigonal bipyramidal geometry, closer to the position of Mn<sub>A</sub> in wild-type MntR.<sup>83</sup> These findings suggest that metal selectivity in the DtxR family is governed by the number and type of ligands bound to the metal, exactly analogous to findings in the MerR- and SmtB/ArsR-family regulators. Interestingly, the amino acid sequence of the putative Zn(II) regulator *T. pallidum* TroR lacks all N-terminal  $\alpha$ 1-derived metal-binding residues that play critical roles in DtxR/IdeR and MntR (Figure 5c); this might explain its reported ability to respond to Zn(II) versus other divalent transition metal ions (Section 3.3.1).

#### 3.3.1 TroR

In 1997, Hardham *et al.* discovered a six-gene cluster termed the transport-related operon (*tro*) from *Treponema pallidum*.<sup>85</sup> Two genes of the operon include TroA, which encodes the solute-binding protein (SBP) component of an ATP-binding cassette transporter, and TroR, a DtxR-like metalloregulator.<sup>85,86</sup> TroR is similar to MntR in sequence (Figure 5c), and has been characterized as both a Mn(II)-specific,<sup>87,88</sup> and a Zn(II)-specific<sup>85,89</sup> regulator *in vivo*. Only limited metal-binding experiments have been reported for TroR, and there is currently no available structure. However, the crystallographic structure of Zn(II)-bound TroA,<sup>86,90</sup> the SBP whose expression is metalloregulated by TroR, may provide some insight as to the natural metal ligand(s) for TroR.

TroA coordinates a single Zn(II) ion in a pentavalent coordination geometry formed by H68, H133, H199 and D279(Oδ1 and Oδ2).<sup>86</sup> This coordination structure differs

**Figure 5** (a) Ribbon representation of the structure of wild-type *B. subtilis* MntR with two Mn(II) ions bound per protomer in a binuclear cluster. One subunit is shaded green and one in red. Residues E11, H77, E99, and E102 coordinate the Mn(II) ion designated as Mn<sub>A</sub> while D8, E11, E102, and H103 coordinate the Mn(II) ion designated as Mn<sub>B</sub>. The Mn(II) ions are bridged by bidentate interactions of E11, E102, and a solvent molecule; (b) structure of D8M MntR with one Mn(II) bound per protomer. One subunit is shown in green and the other in red. Residues E11, H77, and E102 coordinate the Mn(II) ion along with a solvent molecule (not shown); (c) sequence alignment of *T. pallidum* TroR, *B. subtilis* MntR, *C. diphtheria* DtxR, and *M. tuberculosis* IdeR with the secondary structure regions (based upon crystal structure of MntR) shown as above. Known metal-binding residues are colored red and boxed. Proposed metal-binding residues of TroR are shaded green. Note that the metal specificity of TroR (Zn vs. Mn) has not yet been firmly established (see text for details)

from that recently reported for Zn(II)-bound *Synechocystis* 6803 ZnuA, the SBP of the ZnuABC metal transporter, which is highly selective for Zn(II). In ZnuA, Zn(II) is bound in a distorted tetrahedral coordination geometry with just three protein-derived histidines, exactly analogous to H68, H133 and H199 in TroA, and a solvent molecule; the bidentate ligand D279 in TroA is conserved in ZnuAs. Although both ZnuA and TroA belong to the same cluster 9 family of ABC transporters, it has been argued that ZnuA preferentially binds Zn(II) over Mn(II) by providing just three protein-derived ligands, since Mn(II) complexes with low-coordination numbers are essentially inaccessible owing to ligand-field destabilization arguments and the well understood Irving–Williams series; Zn(II) with its full *d*-shell readily adopts four-coordinate complexes.<sup>91</sup> Since TroA apparently binds Zn(II) in a five-coordinate geometry, Mn(II) should bind to TroA with high

affinity as well; this will effectively relax the metal selectivity of this transporter system. This is in fact the case since the measured metal-binding affinities of Zn(II) and Mn(II) ( $K_d = 1.3 \pm 0.4 \mu\text{M}$  and  $K_d = 1.0 \pm 0.2 \mu\text{M}$ , respectively) are identical within experimental error.<sup>89</sup> One would expect that the metalloregulator TroR would have evolved to sense both Zn(II) and Mn(II) as well.

### 3.4 Fur Family: Zur

*E. coli* Fur and homologs in other prokaryotes regulate the transcription of genes required for iron acquisition, including a host of distinct iron scavenging systems as well as the enzymes for siderophore biosynthesis (see **Iron Transport: Siderophores; Metalloregulation**).<sup>80</sup> In addition,

**Figure 6** (a) A ribbon representation of the crystallographic structure of the  $Zn_4$  *Pa* Fur dimer. Blue, DNA-binding domains; green, C-terminal dimerization domain (see text for details). Zinc ions are shown as dark magenta spheres. (Ref. 92. Reproduced by permission of Blackwell); (b) Sequence alignment of *Pseudomonas aeruginosa* Fur, *E. coli* Fur, and *E. coli* Zur using ClustalW (<http://www.ebi.ac.uk/clustalw>).<sup>93</sup> Known metal-binding ligands are boxed and the secondary structural elements are as above. Blue residues in *P. aeruginosa* Fur represent the proposed regulatory Fe-binding site; red residues in *P. aeruginosa* represent the proposed structural Zn binding site

the expression of key virulence factors in pathogenic bacteria are also regulated by Fur. The working model is that the iron-bound form of Fur binds to specific target sequences in the promoter of iron-regulated genes, collectively known as 'iron boxes', blocking access by RNA polymerase. Like the DtxR family regulators, iron functions as a corepressor of the expression of those genes linked to iron acquisition; in iron-starved conditions, these genes are constitutively expressed. The high-resolution crystallographic structure of *Pseudomonas aeruginosa* Fur complexed with  $Zn(II)$  (rather

than iron) has recently been reported to 1.8 Å resolution, with a ribbon representation of the structure shown in Figure 6.<sup>92</sup> The global structure of the Fur homodimer is superficially similar to that of DtxR; in fact the winged-helix DNA-binding domains superimpose with a backbone rmsd of 1.8 Å from helix  $\alpha 2$ - $\alpha 4$  through the  $\beta 1$ - $\beta 2$  hairpin. The dimerization domain of each protomer is an  $\alpha/\beta$  domain consisting of a 3-stranded  $\beta$ -sheet topped by the C-terminal  $\alpha 5$  helix. Dimerization results in a six-stranded  $\beta$ -barrel capped by an antiparallel coiled-coil formed by the  $\alpha 5$  helices.

Two metal ions are bound per protomer for a total of four metal ions per dimer, designated Zn1 and Zn2. Zn1 is coordinated by residues located exclusively in the dimerization domain and adopts a distorted octahedral geometry with four protein-derived ligands (H86, D88, E107 and H124), and includes one bidentate carboxylate (D88) and a well-ordered water molecule. Zn2 bridges the DNA-binding and dimerization domains and adopts distorted tetrahedral coordination geometry (H32, E80, H89 and E100).<sup>92</sup> Fe(II) exchange experiments and characterization of the resulting Zn/Fe hybrid protein by X-ray absorption spectroscopy reveals that Zn1 is readily exchanged with Fe(II) and adopts a coordination complex that is isostructural with Zn1, with coordination of Zn2 unchanged. Therefore, Pohl *et al.* argue that in *Pa Fur*, the regulatory metal site corresponds to Zn1 located exclusively in the dimerization domain, while Zn2 is an unusual structural Zn(II) site, which forms part of the long-range allosteric pathway of communication between the regulatory sites and the DNA-binding domains of *PA Fur*. It seems plausible that metal binding to site 1 might globally alter the orientation of one subunit relative to the other, stabilizing a high-affinity binding conformation. All *Fur* homologs contain the full complement of metal sites structurally characterized in *Pa Fur*.

Interestingly, many *Fur* homologs, including *E. coli Fur*, contain two pairs of cysteine residues not present in *Pa Fur*. One pair is C92 and C95, just C-terminal to H86 and D88 of the Zn1(Fe) site and H89 of the Zn2 site, and N-terminal to E100 of Zn2 site in *Pa Fur*; *Pa Fur* contains a residue analogous to C92 only, which does not participate in metal binding (see Figure 6b). In addition, most *Fur* homologs contain a short C-terminal extension that contains a C-X<sub>4</sub>-C sequence that is not present in *Pa Fur* (Figure 6(b)). X-ray absorption studies of *E. coli Fur* suggest at least one sulfur-containing Zn(II) coordination complex; spectroscopic studies of mutants suggest that C92 and C95 ligate this Zn(II) ion in the formation of a structural S<sub>2</sub>(N/O)<sub>2</sub> complex, although this remains to be definitely determined.<sup>93,95</sup>

#### 3.4.1 *E. Coli Zur*

*Zur* is a recently discovered *Fur* ortholog (27% sequence identity) that regulates the expression of a divergently transcribed operon that encodes the high-affinity zinc uptake system, *znuBC* and *znuA*, in a highly Zn(II)-specific fashion.<sup>96,97</sup> The high-resolution structure of *Zur* is not yet available and the molecular basis for metal ion discrimination by *E. coli Zur* remains unclear. However, it is possible to speculate on metal selectivity on the basis of an amino acid sequence alignment and limited spectroscopic findings reported for the Zn(II) and Co(II) metalloderivatives of *E. coli Zur*. *Zur* binds two metal ions per subunit and four per dimer in two spectroscopically distinguishable tetrahedral sites.<sup>98</sup> One Zn(II) ion, ZnA, is tightly bound in an S<sub>3</sub>(N/O) coordination environment and is refractory to metal exchange with Co(II).

This site is likely analogous to the structural Zn2 site in *Fur* homologs that contain the C92-X<sub>2</sub>-C95 cysteine pair. The other site, ZnB, is readily exchanged with Co(II) and is characterized by tetrahedral S(N/O)<sub>3</sub> coordination geometry, in striking contrast to the octahedral, putative Fe(II)-sensing Zn1(Fe) site of *Fur*.<sup>98</sup> Although the four donor atoms to this putative Zn(II)-sensing site remain unknown, at least two cysteine residues just C-terminal to the  $\alpha 5$  helix in *Pa Fur* appear to be uniquely conserved in all functionally characterized *Zur* proteins (Figure 6b); one of these may well correspond to the thiolate donor in the ZnB site. Regardless of the details, these comparative structural studies of *Fur* and *Zur* emphasize the recurring theme that the primary determinant for metal selectivity in metal sensor proteins is coordination number and geometry, with a lesser role played by the nature of the donor atoms. This is exactly in accord with the conclusions reached by the Fierke group from a careful investigation of the metal affinities and structural studies of an extensive panel of carbonic anhydrase mutants (*see Zinc Enzymes*).<sup>99</sup>

### 3.5 MTF-1 and *S. Cerevisiae Zap1*

Eukaryotic cells, like prokaryotes, have evolved efficient mechanisms to govern metal ion homeostasis, except that the regulatory logic is far more complex than simple regulation of DNA binding. In eukaryotes, metalloreulation of intracellular (cytoplasmic-nuclear) trafficking, posttranslational modification, protein-protein interactions and DNA binding are all possible and have been documented to occur in some cases. Two zinc finger proteins are known to play major roles in regulating zinc homeostasis in eukaryotes. They are *S. cerevisiae Zap1*, which controls the expression of a number of genes (>40) involved in zinc accumulation and storage, and vertebrate metal-response element (MRE)-binding Transcription Factor 1 (MTF-1). MTF-1 up-regulates the transcription of genes encoding metallothioneins, small cysteine-rich metal-sequestering proteins, ZnT-1, a cytoplasmic efflux pump, and other genes in response to heavy-metal (Zn/Cd) and oxidative stress in mammals. Both proteins possess multiple tandem C<sub>2</sub>H<sub>2</sub> zinc fingers (7 zf's in *Zap1* and 6 zf's in MTF-1), a subset of which appears to metalloreulate DNA-binding upon zinc binding (Figure 7).<sup>15,100–102</sup> A cluster of five zinc fingers near the C-terminus of *Zap1* mediates high-affinity binding to an 11-bp zinc-response element (ZRE), while fingers 1 to 4 of MTF-1 play this role on the 12-bp MRE.<sup>101–103</sup>

A popular metalloreulatory model proposes that these or other remaining zinc fingers might regulate gene expression in response to fluctuations in bioavailable zinc concentration. In *Zap1*, zinc fingers zf1 and zf2 appear to play a direct role in zinc sensing by negatively regulating activation domain 2 function as the intracellular zinc concentration rises (see Figure 7).<sup>16</sup> In MTF-1, the precise mechanism of Zn(II)-activation of MRE-binding has been far more elusive, although recent experiments suggest that zinc fingers zf1, zf5, and zf6 stabilize the interaction of MTF-1 with chromatin-embedded

**Figure 7** (a) Domain organization of human MTF-1 in which zinc finger domains are colored yellow and denoted by ZF (zinc finger). The acidic, proline-rich, and Ser/Thr-rich transactivation domains are indicated. *NLS*, nuclear localization signal; *NES*, nuclear export signal; *Cys-rich*, a cysteine cluster that functions in metal-inducible transcriptional activation;<sup>104</sup> (b) Domain organization of *S. cerevisiae* Zap1. Transactivation domains are indicated as is the DNA-binding domain (zf3-zf7)<sup>16</sup>

MREs.<sup>100,105</sup> Interestingly, all six zinc fingers of hMTF-1 bind Co(II) with equilibrium affinities that are more similar than different ( $K_{Co} \approx 2 \times 10^6 - 5 \times 10^7 \text{ M}^{-1}$  at pH 7.0),<sup>106</sup> despite the vastly different reactivities of the cysteine thiolates of C-terminal fingers zf5 and zf6 toward an exogenous alkylating reagent, that is, these fingers exhibit an enhanced kinetic lability relative to primary MRE-binding fingers. Likewise, a peptide corresponding to the regulatory fingers (zf1-zf2) of Zap1 binds Zn(II) with the same apparent affinities as a DNA-binding finger pair (zf3-zf4) ( $K_{Zn} \approx 10^9 \text{ M}^{-1}$ ) despite more rapid metal dissociation rates for the zf1-zf2 pair.<sup>16</sup> These findings suggest that zinc metalloregulation of gene expression in eukaryotic cells might be under kinetic, rather than thermodynamic control (see Section 4). Recently, it has been shown that a conserved cluster of four cysteines (<sup>632</sup>CQCQCAC<sup>638</sup>) located just C-terminal to the Ser/Thr-rich transcription activation domain of hMTF-1 (see Figure 7) is required for activation of transcription in the presence of zinc and cadmium *in vivo*.<sup>104</sup> These findings suggest that other domains outside of the zinc fingers themselves in MTF-1 play a role in metal inducibility. MTF-1 and Zap1 utilize their zinc fingers to bind DNA with high affinity and help regulate the expression of genes involved in metal sequestration and/or transport. Exactly how these domains regulate transcription in response to changes in intracellular zinc concentration still requires clarification.

#### 4 PERSPECTIVES/CONCLUSIONS

As summarized in this chapter, zinc-containing nucleic acid-binding proteins are ubiquitous in nature and play integral roles in all aspects of nucleic acid metabolism, including DNA replication, recombination and repair, transcriptional

activation/repression and chromatin remodeling, translational regulation, mRNA stability, ribosome dynamics and biogenesis. Although the molecular structures of these zinc coordination complexes are remarkably diverse and encompass all  $\alpha$ -, all  $\beta$ - and mixed  $\alpha/\beta$ -domains (Table 1), the common feature is a tetrahedral coordination geometry formed by four protein-derived ligands, two or more of which must be cysteine thiolates. Formation of the zinc coordination complex directs the folding of what are often mini domains that typically lack a hydrophobic core, thereby functionally stabilizing protein-protein and protein-nucleic acid interfaces. The classification of these zinc finger proteins into distinct fold groups begs the question of how many additional novel structures of zinc finger proteins might exist. Section 2.8 lists several proteins that do not precisely adhere to the structural classification scheme summarized in this chapter. However, global examination of their structures seems to suggest that as new zinc finger or zinc fingerlike domains are characterized, they will likely have some similarity to existing fold groups already described.

Is there additional functional currency that comes with the specific utilization of thiolate-rich Zn(II) coordination complexes to fulfill these myriad of important roles? One possibility may lie in the distinctive features of Zn-thiolate chemistry itself.<sup>107</sup> There is emerging evidence in support of the idea that zinc sites in nucleic acid-binding proteins are susceptible to rapid, and in some cases, reversible inactivation via formation of disulfide bonds between metal-ligating cysteines, with concomitant expulsion of the Zn(II) and local unfolding, under conditions of oxidative stress. For example, cysteine thiolates are readily *S*-nitrosylated when intracellular NO concentrations in mammalian cells rise; in at least one case, increasing NO gives rise to transient increases in intracellular zinc levels that is detectable by zinc-selective intracellular dyes.<sup>108</sup> In addition, *S*-nitrosylation of the RING finger domain

(Section 2.3) of a ubiquitin E3 ligase *parkin* is positively linked to neurodegenerative loss of dopamine neurons in Parkinson's disease.<sup>109</sup> A similar perturbation of zinc pools by heavy-metal xenobiotics, for example, Cd, in mammalian cells has also been proposed.<sup>40</sup> These and other findings suggest a strong link between intracellular zinc levels and various stress responses and the progression of human disease perhaps mediated in part by zinc release from metallothioneins, with Zn-thiolate coordination bonds a 'composite' redox sensor, rather than the metal ion itself, which obviously does not change oxidation state.<sup>107</sup> Such a redox sensor might also transiently disable fundamental processes devoted to DNA replication, DNA recombination, transcription initiation and regulation, and ribosome biogenesis until a full-scale redox stress response could be mounted by the cell.

Interestingly, metalloregulatory zinc sites in prokaryotic and mammalian metal sensor proteins, like structural zinc finger complexes, often contain thiolate ligands as well; in fact, homologous SmtB/ArsR sensors *Synechococcus* SmtB and *S. aureus* CzrA are currently the lone exceptions to this trend (Section 3.2.1). In these systems, zinc coordination number, rather than ligand type, appears to dictate metal selectivity among closely related orthologs from different metal sensor families (Section 3). The common structural feature is that metalloregulatory zinc sites, like structural zinc finger sites, are rigorously four-coordinate, but may be characterized by perhaps one weakly bound metal ligand that would enable ligand exchange and zinc transfer to acceptor proteins in establishing metal resistance.<sup>94</sup> This may be particularly important for zinc sensors since the thermodynamic stabilities of these zinc regulatory proteins are high (pM and fM zinc dissociation equilibrium constants for SmtB and ZntR/Zur, respectively).<sup>110,111</sup> This makes it unlikely that zinc will move from donor to acceptor, be it protein, metallothionein or small molecule (reduced glutathione), via the solvent and may instead be directly transferred from donor to acceptor in a process characterized by an equilibrium constant near one that might be kinetically facilitated by transient docking and rapid ligand exchange. This would have the effect of maintaining zinc homeostasis even upon challenge with toxic concentrations of the metal in the absence of large thermodynamic gradients of 'free' zinc inside the cell or within other intracellular compartments. Obtaining a mechanistic understanding of zinc homeostasis and trafficking within living cells in normal versus stressed states will surely prove to be an exciting area of future work in the general area of zinc and nucleic acid-binding proteins.

Enzyme acting on peptides; PINCH = Particularly interesting new Cys-His protein; PLBP = Periplasmic ligand-binding protein; PMI = Phosphomannose isomerase; PTS = Signal transducing protein; PsaA = Pneumococcal surface antigen; Proteinase = Enzyme acting on proteins; RS = tRNA synthetase; SAM = S-adenosyl-L-methionine; SEA, B etc. = Staphylococcal enterotoxins type A, B etc; SPEA, C etc. = Streptococcal pyrogenic exotoxins type A, C etc; SET = Su(var), Enhancer of zeste, Trithorax; SHBG = Sex hormone binding-globulin; SMEZ = streptococcal mitogenic exotoxin; Sir2 = Silencing information regulator 2; SOD = Superoxide dismutase; TCR = T-cell receptor; TNF = Tumor necrosis factor; TACE = Tumor necrosis factor- $\alpha$ -converting enzyme; TSST = Toxic shock syndrome toxin; VanX = Dipeptidase of vancomycin-resistant pathogenic *Enterococci*; VDR = Vitamin D-Receptor; XAFS = X-ray absorption fine structure; XIAP = X-linked inhibitor of apoptosis protein.

---

## 1 INTRODUCTION

The importance of zinc to growth and development in all forms of life was first established through zinc deficiency studies of microorganisms followed by those in plants and animals (*see Nutritional Aspects of Metals & Trace Elements*).<sup>1</sup> The involvement of zinc in a wide variety of metabolic processes including carbohydrate, lipid, protein, and nucleic acid synthesis and degradation paralleled the technical advances in analytical methods that could detect the presence of zinc in minute amounts coupled with advances in the methodology for protein isolation and purification.

The molecular characterization of zinc sites in biological systems came first through replacing the spectroscopically silent zinc with the chromophoric metal cobalt. These studies in conjunction with kinetic studies gave information on the importance of the metal site to protein function. Structural studies of the entire protein obtained by X-ray diffraction and NMR now give detailed information of the metal ligands and the coordination geometry of the metal site. X-ray absorption fine structure, XAFS, permits visualization of the zinc site directly in the solution and crystal states and enhances the ability to identify the manner in which zinc is involved in the function of the protein.<sup>2</sup> The combination of all of these approaches allows formulation of how the zinc influences protein function that can be tested by a combined approach including mutagenesis and rapid kinetics. Finally, the ability to determine primary protein structure through translation of DNA sequences in combination with our increasing knowledge of zinc-binding sites permits prediction of new zinc-binding sites and thereby protein function without even having an expressed protein.<sup>3,4</sup>

Zinc is the only metal to have representatives in all six of the International Union of Biochemistry, IUB, classes of

enzymes. The function of these enzymes is therefore related to the chemistry of zinc, which is quite versatile. It has a remarkably adaptable coordination sphere that allows it to accommodate a broad range of coordination numbers and geometries. If zinc retains a positive charge after ligating to protein side chains, it can act as a Lewis acid in catalysis. If a zinc-bound water is converted to hydroxide, the zinc site can act as a base or nucleophile in catalysis. In this sense, the zinc sites are amphoteric. The oxidation/reduction properties of its neighboring transition metals is a major cause of their ligand exchange rates, amphoteric properties, and coordination geometries. Since zinc has a filled *d*-shell, it does not have oxidation/reduction properties, thus providing a stable metal ion species in a biological medium whose redox potential is in constant flux.

Our first attempts at classifying the manner in which zinc binds to enzymes was made on the basis of the zinc ligands and coordination geometries of from one to three dozen zinc enzymes during the period 1988 to 1993 (Figure 1). This led to the recognition of three types of zinc-binding sites: *catalytic*, *cocatalytic*, and *structural*.<sup>5,6</sup> As of 2003, the structural characteristics of more than thirty dozen zinc sites have been reported, the great majority of which still fit into the original classification (see below). A new type of zinc-binding site, *protein interface*, has become apparent during the past few years.<sup>3,4</sup> In this case, zinc-binding sites are formed through ligands supplied from amino acid residues residing in the binding surface of two protein molecules.

## 2 SOME GENERAL FEATURES OF ZINC-BINDING SITES

The secondary support and scaffolding in combination with the direct ligands of the zinc allows fine tuning of the role of the zinc and its neighboring amino acids in the protein function. The following general observations pertain to the structural properties of zinc-binding sites found in enzymes and other zinc-binding proteins.<sup>4</sup> (1) Nearly all the zinc sites contain at least one secondary structural element. (2)  $\beta$ -sheets supply

**Figure 1** Time course of structural determination of zinc-binding sites in enzymes

ligands to a wide variety of zinc-binding sites. (3) Ligands frequently come from the first, last, or 1 or 2 amino acids before or after a  $\beta$ -sheet or  $\alpha$ -helix. (4) Small loop regions (6 amino acids) between two types of secondary structure can also supply the ligands. This may allow more freedom in the coordination properties of the zinc site. (5) Short spacers of one generally use a  $\beta$ -sheet to supply the ligands while a spacer of three uses an  $\alpha$ -helix. (6) An  $\alpha$ -helix is used to supply the short spacer ligands most frequently in hydrolytic enzymes (in particular, the metalloproteases). (7) His ligands are often H-bonded to carboxyl groups of Asp or Glu or carbonyl groups of a variety of amino acids. (8) Hydrophobic amino acids likely are involved in stabilizing the zinc-binding site through orientation of the ligands.

## 3 CATALYTIC ZINC SITES

There are today about 12 dozen 3-dimensional structural references of *catalytic* zinc sites encompassing all six classes of enzymes (Table 1). The hydrolase enzyme class (III) has the greatest number of representatives. A catalytic zinc generally forms complexes with any three nitrogen, oxygen, and sulfur donors of His, Glu, Asp, and Cys with His being the predominant amino acid chosen. Histidine (usually the NE2 nitrogen) may be chosen because of its capacity to disperse charge through H-bonding of its nonliganding nitrogen. The overall sequence length of such sites can be as small as 11 amino acids as is observed in the zinc endoprotease families with the zinc site signature HExxHxxGxxH/D and the 5-aminolevulinic acid dehydratase enzymes (Table 1). The zinc ligands are separated by comparatively short and long amino acid spacers. While in principle the third ligand could be supplied from either the C- or N-terminal side of the first two ligands, the C-terminus is preferred by a ratio of about 5 to 1. The great majority of the short spacers contain one to three amino acids (Table 1). The length of the short spacer is often dictated by the ligand support structure: 3 for an  $\alpha$ -helix and 1 for a  $\beta$ -sheet. In the case of the oxidoreductases, the involvement of H-bonding interactions between residues in the short spacer (for example, His47 and/or His51 in ADH) and the cofactor reduced nicotinamide adenine dinucleotide (NADH) may have led to the extension of the 'short' spacer to 17 to 29 (versus a long spacer of 82 to 106).

The coordination number for such sites is usually 4 or 5 and the geometry in the free state is frequently distorted-tetrahedral or trigonal-bipyramidal. Water is always a ligand to the catalytic zinc. The zinc-bound water can be directly involved in catalysis by its ionization or it can be activated through polarization by a neighboring amino acid residue acting as a general acid/base (Figure 2). The zinc can function as a Lewis acid by a substrate ligand displacement by the water or expansion of the coordination shell. The chemical nature of the three protein ligands, their spacing and secondary

<sup>a</sup>The amino acid spacer between ligands L<sub>1</sub> and L<sub>2</sub> is X, that between L<sub>3</sub> and nearest ligand L<sub>1</sub> or L<sub>2</sub> is Y, and that between L<sub>3</sub> and L<sub>4</sub> is Z. The symbol N indicates that L<sub>3</sub> is located on the amino (N) side of L<sub>2</sub>. If no letter is present, L<sub>3</sub> is located on the carboxy-terminal side of L<sub>2</sub>. The subscripts α, β refer to the α- or 3<sub>10</sub> helix and β-sheet structure that supplies the ligand. The subscript L denotes an amino acid sequence of ≤ 6 residues between two structural elements. The subscripts a and b indicate the ligand is either one (or two) residues after or before the secondary structural element.

**Figure 2** The role of the zinc and its bound water in catalysis. The water can ionize either (a) without or (b) with the help of an adjacent base, B, supplied by an amino acid residue. The zinc-bound water can also (c) be displaced by substrate, S or (d) the coordination sphere be expanded upon interaction with substrate

interactions with neighboring amino acids in conjunction with the vicinal properties of the active center created by protein folding are all critical for the various mechanisms through which zinc can be involved in catalysis.

### 3.1 Scaffolding of the Catalytic Zinc Sites

In considering how tightly the zinc will bind to the protein site, how readily it can be released from the protein, and its effect on protein function one must not only take into account the first shell ligands but the scaffolding of these sites. The scaffolding encompasses not only the type of secondary structure supplying the ligands, but also the effects of amino acid residues on the metal ligands. These amino acids are sometimes thought of as the ‘outer or second’ shell of ligands. Indeed comparative structural studies of the metal sites in four of the first known zinc enzymes, carbonic anhydrase, carboxypeptidase A, alcohol dehydrogenase, and thermolysin led to the identification of carbonyl and carboxyl ‘orienters’, or amino acids that formed H-bonds to the ligands to the metal.<sup>7</sup>

Many of the catalytic and structural zinc-binding sites contain His imidazole and Glu or Asp carboxyl groups as ligands to the zinc. The tight binding and often slow off rates for zinc from such sites is not expected based on the binding constants for imidazole and acetate binding to zinc. The  $pK_1$  values for acetate and imidazole of  $\sim 1.5$  are not particularly strong.<sup>2</sup> Binding three imidazole groups and an acetate to a zinc would then be expected to have an overall binding constant of  $10^5$ – $10^7$ . However, the binding constant for zinc to the Thr199Glu mutant carbonic anhydrase II<sup>8</sup> that contains 3 His and 1 Glu as ligands is  $5 \times 10^{13}$ . The fact that

so many catalytic zinc sites bind zinc with picomole binding constants, yet have imidazole and acetate as their ligands likely reflects their proximity and restricted mobility in the protein. A regular form of secondary structure can supply some of the correct orientation needed for good ligand binding to zinc. However, the stability and the function of the metal site is also likely influenced by the outer shell of residues in the vicinity of the metal-binding site. The secondary interactions of the ligands with ionic groups of the side-chain groups of the outer shell amino acid residues or the carbonyl oxygen of the backbone peptide chain may be critical to the formation and stabilization of the zinc sites containing oxygen, nitrogen, and sulfur ligands.

#### 3.1.1 Carbonic Anhydrases: Hydrophilic Orienters

Examination of the effect of the orienters or indirect ligands on stability of the zinc-binding site and catalysis has been most thoroughly examined in the carbonic anhydrase  $\alpha$ -class of enzymes.<sup>9,10</sup> There are currently X-ray crystal structures for catalytic zinc-binding sites of 5 of the mammalian  $\alpha$ -carbonic anhydrases (Figure 3). The zinc ion is coordinated by the imidazole side chain of His94, His96 and His119 in all of these mammalian carbonic anhydrases. The three His ligands

**Figure 3** Zinc ligands of mammalian carbonic anhydrases, CA I-V. Names denote type and species of CA. Data obtained using the sequence of human CA I and the resources of the EMBL computer center<sup>3</sup>

**Figure 4** Catalytic zinc-binding site of human carbonic anhydrase II (pdb# 1CA2<sup>12</sup>) showing the zinc ligands NE2 of His94 and His96 and ND1 of His119 and their oxygen atom 'orienters' from Gln92, Asn244, and Glu117 respectively. Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

of these enzymes readily allow formation of zinc hydroxide, which can then add  $\text{OH}^-$  to  $\text{CO}_2$  to form  $\text{HCO}_3^-$ . The amino acids adjacent to these zinc ligands are also highly conserved compared to the rest of the protein.<sup>3</sup> Thus, while the similarity scores for this set of proteins is between 60 to 99% the metal-binding site ligand sequence (9 amino acids used for each region) is above 90% for the majority of the sequences. In terms of identity of amino acids the overall structures are 35 to 95% identical while the metal-binding site sequences are 60 to 100% conserved. One of the reasons for this is that H-bonds are formed between Gln92 amide nitrogen and His94 and between the Glu117 carboxyl group and His119 (Figure 4). These interactions likely stabilize zinc binding and influence the function of the zinc in catalysis. In addition, the backbone carbonyl of Asn 244 accepts a H-bond from His96 and the hydroxyl group of Thr199 accepts a hydrogen bond from the zinc-bound water.<sup>11</sup> These residues are also conserved in all the carbonic anhydrase I-V enzymes.

Secondary ligand interactions are postulated to be involved in strengthening the metal complexation and/or modulating the nucleophilicity of the zinc-bound water.<sup>13</sup> Both interactions occur in the case of carbonic anhydrase based on the examination of functional and structural consequences of mutating the orientating residues Gln92, Glu117, Asn244 and Thr199.<sup>11,14,15</sup> The results indicate the zinc affinity is reduced by about a factor of five- to ten-fold when a native H-bond is eliminated. The effects also appear to be additive. Thus, the combined mutations of Gln92Ala and Glu117Ala leads to a 40-fold increase in the dissociation constant for zinc while the individual mutations lead to 4- and 10-fold increases, respectively.<sup>11</sup> The weakened binding of zinc is largely accounted for by an increased off-rate constant for zinc dissociation.

These secondary protein interactions would also be expected to affect the charge on the zinc. The interaction

of hydrogen donating or accepting groups to the zinc ligands might therefore modulate the  $\text{pK}_a$  of the catalytic zinc-bound water resulting in changes in the nucleophilicity of the water and the ease at which it can expand its coordination shell or allow the zinc-bound water or hydroxide to be displaced. The pH dependence of the carbonic anhydrase II catalyzed hydrolysis of *p*-nitrophenylacetate was used to examine this postulate. In the wild type enzyme, it is characterized by a  $\text{pK}_a$  of 6.8, which is believed to reflect the ionization of the zinc-bound water molecule.<sup>11</sup> In the case of the Gln92Glu mutation in carbonic anhydrase II, a neutral hydrogen bond acceptor is replaced by a negatively charged acceptor. The positive charge on the zinc should therefore be reduced, which in turn should make the ionization of the water more difficult. The results of the functional studies confirm this relationship since the kinetically determined  $\text{pK}_a$  for the water increases by 0.7 units for this mutation.<sup>11</sup>

The reverse effect is expected for a mutation that removes this negative charge since this should increase the charge on the zinc leading to a lower  $\text{pK}_a$  for ester hydrolysis. Replacing Glu117 with Asp led to a slight decrease of 0.2 units consistent with a less favorable interaction of the Asp117 carboxylate with the His119 imidazole group. However, the results with Glu117Ala did not agree with the expectations. The  $\text{pK}_a$  values for the native and Glu117Ala mutant are 6.8 and 6.9 respectively. The value for the Ala mutant was expected to be lowered by as much as 1 unit owing to the loss of the anionic interaction with the His ligand. The X-ray studies found a chloride ion binding in the crystalline Glu117Ala mutant in the region of the Glu-117 carboxylate-His-119 interaction of the native enzyme.<sup>15</sup> The kinetic assays didn't contain any chloride ions but did use 0.1 M sulfate for controlling ionic strength.<sup>11</sup> If sulfate can bind in the same region as chloride, His119 may still have an interaction with an anionic species.

However, inspection of the X-ray structure of the native enzyme suggests another explanation (Figure 5). There are

**Figure 5** H-bonds to the side-chain carboxyl group of Glu117 of human carbonic anhydrase II (pdb# 1CA2<sup>12</sup>). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

several potential H-bonds for the carboxyl group of Glu117 with other amino acids in its vicinity in the native enzyme. Thus, the OE2 of Glu117 is 2.57 Å and 2.93 Å from the NE2 of His119 and ND1 of His107, respectively (pdb # 1CA2<sup>12</sup>). In addition, the OE1 of Glu117 is 2.83 Å and 2.87 Å from the amide NHs of both His107 and Glu106. This intricate pattern of H-bonds would be expected to reduce the effect of relaying negative charge to the zinc ligand His119. Removal of this carboxyl group would therefore not be expected to change the charge on the His ligand in agreement with the results. The loss of the extensive H-bonding network to this ligand might be expected to be reflected in a relaxing of the conformation of this ligand, which could in turn lead to an increased off-rate for zinc dissociation. This is in fact what occurs for mutations of this ligand in contrast to the same mutations for His94 that does not have as extensive H-bonding network. Thus, the conversion of His94Ala leads to a 2-fold increase in the off-rate constant for zinc dissociation, while that for His119Ala leads to a 300-fold increase.<sup>11</sup> It is also of interest to note that a new H-bond is gained in the mutation of Gln92Glu. In this case, the OE1 oxygen of the carboxyl group of Glu92 is 2.94 Å from ND1 of His94 and is 3.01 Å from the amide NH of Phe93. This would tend to reduce the effect of relaying negative charge to the zinc and might place more constraint on the zinc ligand, His94, in the mutant enzyme. The fact that the zinc off-rate constant is now 6-fold slower than that of the native enzyme<sup>11</sup> is consistent with the increased H-bonding network found in the mutant enzyme.

### 3.1.2 Carbonic Anhydrase: Hydrophobic Orienters

The hydrophobic residues at positions 93, 95 and 97 are also highly conserved for this family of enzymes (Figure 3).<sup>3</sup> These residues are generally Phe for positions 93 and 95 and Trp for 97. The aromatic residues would be expected to restrict the motion of the His ligands and/or provide an environment of low dielectric constant that would enhance electrostatic interactions.<sup>16</sup> A cassette mutagenesis technique was used to select CA II enzymes mutated at positions 93, 95 and 97 that retained high zinc affinity.<sup>17</sup> The best variant enzymes contained Ile, Phe, Leu, and Met at position 93; Ile, Leu, and Met at position 95 and Trp or Val at position 97 in general agreement with what is found for this class of enzymes. When small hydrophilic residues are introduced at these positions, the zinc affinity decreases. Thus, the Thr-His-Ser-His-Val mutant compared to the native Phe-His-Phe-His-Trp enzyme has a 110-fold increased  $K_D$  for zinc essentially owing to an increase in the off-rate constant of 400-fold. The  $k_{cat}/K_m$  for the CO<sub>2</sub> hydrase and esterase activity is decreased 90- and 30-fold, respectively, but the  $pK_a$  for esterase activity doesn't change. The better zinc-binding and higher catalytic efficiency correlate with the combined volume of the residues at positions 93, 95, and 97.<sup>17</sup>

The effect of these amino acids on the zinc dissociation rate constant was also examined. Replacement of the hydrophobic

**Figure 6** Amide of Met241 of human carbonic anhydrase II H-bonds to the indole NH of Trp100 (pdb# 1CA2<sup>12</sup>). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

amino acid by Ser at any position increased the zinc off-rate constant. The results suggested replacing the large aromatic residues at positions 93, 95, and 97 with smaller residues may increase the conformational mobility of the  $\beta$ -strand, permitting the adjacent histidines that coordinate zinc (His94 and His96) additional flexibility.<sup>18</sup> The variants with the slowest dissociation rate constant retain Trp at position 97. Comparison of the properties of the variants Ile 93 Met 95 Trp 97 and Ile 93 Met 95 Val 97 shows the affinity constant values for zinc are comparable, whereas the zinc dissociation rate constant increases 10-fold for substitution of Trp 97 with Val in agreement with the postulate of the aromatic residues anchoring the  $\beta$ -strand to reduce the conformational flexibility of His94 and His96 metal ligands.<sup>18</sup> The reason Trp97 is able to do this better than a Phe residue may be due to its indole NH. Inspection of the X-ray structure of the native enzyme (pdb # 1CA2<sup>12</sup>) indicates this NH is within H-bonding distance (2.75 Å) from the backbone amide carbonyl oxygen of Met241 (Figure 6). This amino acid is the last residue of a short (3-residue)  $\beta$ -strand and two amino acids removed from Asn244 that H-bonds His96 through its side-chain amide group. Disruption of this H-bond may therefore have an added effect on the increased zinc off-rate constants whenever Trp97 is replaced by other amino acids.

The results of studies of the cobalt- and copper-substituted mutants have indicated these hydrophobic residues may be important to retaining a tetrahedral geometry for the zinc site.<sup>18</sup> The correlation of the additive hydrophobicity of the amino acids bordering the metal ligands to copper binding strength is the reverse of that observed for zinc and cobalt. The lower their collective hydrophobicity the better the copper binding. The mutant enzyme Thr93Ser95Val97 binds copper  $8 \times 10^5$  times more tightly than zinc. The inactive copper-substituted native enzyme has a bipyramidal geometry.<sup>19</sup> The results suggest the hydrophobic cluster of amino acids orients the His ligands to stabilize a distorted-tetrahedral geometry and to destabilize the bipyramidal geometry observed when copper binds.<sup>18</sup>

Although copper binds tighter than zinc to all forms of the enzyme tested, zinc stabilizes the protein fold better as judged by solvent-induced denaturation experiments. In addition the dissociation rate constant for zinc is about 100 times slower than copper suggesting the zinc is kinetically trapped once folding has occurred. This may thus be a physiological means by which metal ion specificity is achieved.<sup>18</sup>

### 3.1.3 Metalloproteases

The closely linked family of carboxypeptidases, CPD, and large group of proteases sharing an HExxH zinc signature serve to illustrate the variation in the level of scaffolding even in such closely related enzymes.<sup>20</sup> The CPD A family includes the A1-A5, B, B3, and U (R) enzymes (MEROPS M14A family)<sup>21</sup> while the CPD E family contains the D, E, X1, X2, and Z enzymes (MEROPS M14B family).<sup>21</sup> Both carboxypeptidase subfamilies show strong conservation of the ligands to the zinc (Table 1) and have an Asp residue from the C-terminal side of the first His ligand that H-bonds to its nonmetal bound NH (Table 2). This residue is conserved in 90 of the 92 sequences reported. This interaction will likely stabilize the zinc-binding site and make the ionization of the zinc-bound water more difficult since the negative charge on the carboxylate oxygen will be transmitted to the metal through the aromatic imidazole ring. The M14 subclasses of carboxypeptidases differ in some likely important aspects in their secondary ligand shell. The residues on each side of the second ligand, L<sub>2</sub>, of the short spacer for the CPD A class are Arg71 and Trp73. The Arg residue is invariant in 56/56

sequences and the Trp residue in 53/56 (3 are His) sequences. In the case of the CPD E class, the L<sub>2</sub> minus one residue is Asn or Asp in 34/36 sequences while the residue equivalent to Trp73 varies considerable and is generally much smaller (15Val, 9Ala, 5Thr, 5 Pro, 1E, and 1 W). Trp residues can often stabilize the zinc binding to its ligands (see above) so its replacement by relatively small amino acids could destabilize zinc binding and/or increase the off-rate constant for zinc. The replacement of the positive Arg residue by a negatively charged Asp or neutral Asn residue would also effect the charge in the active site, which in turn could effect specificity and function of the enzyme.

A large number of the catalytic zinc sites in metalloproteases have either two His and a Glu or an Asp or three His ligands (Table 1). It is therefore generally assumed these sites behave the same with respect to the stability and catalytic function of the metal. However, the scaffolding differs even in relatively closely related family groups (Table 2). Thermolysin, neprilysin, mono-zinc aminopeptidases (represented by leukotriene hydrolase), matrix metalloproteinases, snake venoms (ADAMS), astacin and serriatia all have an HExxH metal-binding sequence containing the catalytic group Glu. Nevertheless, they all differ in the type of H-bonding interactions that occur with the His ligands of the short spacer (Figure 7).

The catalytic zinc site of thermolysin contains His142 and His146 from the short spacer and Glu166 from the long spacer arm. In this case two other conserved amino acids from the long spacer arm make interactions with the ligands from the short spacer arm. Thus, the carboxamide group of Asn165

<sup>a</sup>X-ray structures (Table 1) and the sequence information in the MEROPS 1.7 database<sup>21</sup> are source of information.

H-bonds His146 and the carboxylate of Glu170 H-bonds the NH of His142. Both residues are highly conserved (Table 2). In the neprilysin family, two acidic (Asp) amino acids that are supplied by the short and long spacer arms serve this function. The replacement of the Asn amide H-bonding group observed in thermolysin by an Asp carboxylate group in neprilysin should change the charge on the zinc.

A bifunctional zinc metalloenzyme, Leukotriene A4 hydrolase, catalyzes the rate-limiting step in the biosynthesis of leukotriene B4, a classical chemoattractant and immune-modulating lipid mediator.<sup>22</sup> It also acts as an aminopeptidase and is inhibited by aminopeptidase inhibitors. It has been placed in the aminopeptidase M1 class<sup>21</sup> based on its sequence similarities to aminopeptidases. It uses the carboxylate of Glu235 and the OH of Thr321, residing in the C-terminal arm of the third ligand, to H-bond to the first two His ligands (Table 2). The Thr likely H-bonds through the oxygen to the NH of the His ligand, which should remove charge from the zinc but not as much as a carboxylate. Thr321 is conserved in all 11 of the identified leukotriene enzymes but in the greater M1 class this residue is not highly conserved being Ala in several. The Glu325 residue in LTA4 hydrolase is also conserved in 11/11 sequences while in the greater aminopeptidase class this residue is Glu in several, replaced by Asp for the Ala aminopeptidases and varies greatly for 30 members of the 141 sequence-postulated aminopeptidases.

A superfamily of metalloproteases, encompassing the protease classes<sup>21</sup> M10A&B and M12A&B use backbone amide carbonyls to H-bond the first two His ligands (Table 2). The amide carbonyl of the residue 3 amino acids away from the second His ligand on its C-terminal side H-bonds this His in all the subclasses. It is a highly conserved Leu for members of M10A&B and either a Phe/Ile or Met for the majority of the members of the M12A&B (Table 2). The first His is also H-bonded by an amide carbonyl of a hydrophobic aliphatic amino acid with spacers characteristic of each subclass of protease, varying from 16 to 53 amino acids away. The use of amide carbonyls to H-bond the His ligands would increase the positive charge on the zinc compared to the use of one or two carboxylates for the thermolysin and neprilysin families (Table 2). This in turn could favor the ionization of the zinc-bound water and the use of hydroxide as a nucleophile.

Similar scaffolding interactions occur in the cocatalytic sites of aminopeptidases as well (Table 2). A second type of interaction occurs in many of these sites. When only one of the oxygens of an Asp or Glu ligand binds the metal the other oxygen forms a H-bond with a Ser or Gln or its isosteric amino acid His. The particular type of interactions are again highly conserved and characteristic of the class of peptidase.

These secondary ligand interactions will likely effect the stability of the zinc site, the dissociation rate constant for zinc and the manner in which zinc participates in catalysis. Thus disruption of these interactions could lead to weakened

metal binding and inactivation of the enzyme. If the secondary ligand changes the charge on the catalytic metal, it will change the capacity of the metal to act as a Lewis acid catalyst as well as effect its ability to influence the ionization of the metal-bound water.

### 3.2 Inhibition of Zinc Enzyme Catalysis

Since the zinc-bound water is one of the most critical components of the catalytic zinc site, there are three ways that one can envision inhibiting the metalloenzyme. Thus inhibition should occur if a potential inhibitor can displace the water by binding directly to the zinc, or remove the zinc ion from the protein or bind a second zinc ion to the catalytic zinc-bound water and/or another catalytic group (Figure 8).

#### 3.2.1 Inhibition of Catalysis by Removing the Zinc-bound Water or the Zinc

The importance of zinc enzymes in both normal and pathological processes makes them targets for drug design. The active-site zinc in these enzymes is a particularly attractive target because the strength of a chelator-metal interaction increases the potency and specificity of an inhibitor. Zinc metalloprotease inhibitors are usually designed to inactivate the enzyme by displacing the zinc-bound water and forming a stable ternary complex with the enzyme and active-site zinc. The success of this approach with the angiotensin-converting enzyme (ACE) inhibitor Captopril ([2S]-N-L-3-mercapto-2-methyl-propionyl-L-proline) on the treatment of hypertension<sup>23</sup> led to the design of many types of metal-binding agents that displace the metal-bound water and in addition are designed to mimic the transition state of the enzyme. Popular groups are hydroxamates and thiolates for the C-terminal side, phosphoryl groups for the N-terminal side

**Figure 8** Inhibition of zinc metalloenzymes is accomplished by: (a) an Inhibitor displacing the zinc-bound water, (b) removing the metal, or (c) bridging an inhibitory zinc to the catalytic zinc

and carboxyalkyl and phosphinic acids as transition state or tetrahedral intermediate mimics.<sup>24</sup> Specificity can be built into the inhibitor on either side of the metal-binding ligand. Many of the crystal structures of zinc enzymes reported in the literature are in fact ternary complexes where the zinc-bound water has been displaced by the inhibitor. An excellent source of information on natural metalloprotease inhibitors is the MEROPS protease database.<sup>21</sup>

While there has been extensive research on inhibitors that bind by displacing the catalytic zinc-bound water, relatively little is known about the molecular mechanisms of how a metal-binding agent or chelator removes zinc.<sup>25,26</sup> In most cases, the zinc dissociation rate constant for the metalloenzyme is the controlling factor for such inhibition. D-penicillamine (D-PEN), a drug used for many years in the treatment of rheumatoid arthritis and Wilson's disease (see *Metal-related Diseases of Genetic Origin*), was recently shown to be capable of catalyzing the removal of the metal from zinc proteases.<sup>27</sup> It is a member of the Cys family of amino acids. It differs from D-Cys by the presence of two methyl groups on the  $\beta$ -carbon. D-Cys inhibits carboxypeptidase A by displacing the zinc-bound water as might be expected since it contains a sulfhydryl binding group.<sup>28</sup> D-PEN in marked contrast inhibits by increasing the zinc dissociation rate constant for CPD by 420-fold and then acting as the receptor of the freed zinc ion.<sup>27</sup>

Complete removal of zinc and thus inactivation of the enzyme can be accomplished in these systems at low D-PEN concentrations if a secondary scavenger chelator is added to the system. Such chelators bind metal that has been released from the enzyme but do not participate in the release.<sup>25,26</sup> In the case of carboxypeptidase A,  $\mu$ M thionein (apo-metallothionein; see *Metallothioneins*) inhibits catalysis by only about 10% over a 15-min period consistent with its action as a secondary chelator.<sup>3</sup> However, in the presence of 250  $\mu$ M D-PEN and  $\mu$ M thionein total inhibition is achieved in less than 15 min. D-PEN accelerates zinc equilibration between carboxypeptidase A and thionein (Scheme 1). This is accomplished by D-PEN catalyzing the release of Zn from the enzyme. Since D-PEN is in vast excess over both the enzyme and thionein, the enzyme-released zinc would be expected to bind to D-PEN first. However, since thionein binds zinc more tightly than D-penicillamine and can accept 7 moles of zinc per mole of thionein, it should be the ultimate acceptor of the released zinc.

Consequently, the *in vivo* potency of D-PEN as a zinc enzyme inhibitor can be augmented by coadministration

of secondary chelators or through the presence of natural chelators such as thionein or other metal-binding species. From a physiological perspective, such a mechanism of inhibition would be essentially irreversible, given the minuscule levels of *free* zinc believed present in the body.<sup>29</sup>

### 3.2.2 Inhibition of Enzyme Catalysis by Zinc

Investigations into the metalloenzyme nature of an enzyme frequently involves an attempt to inhibit it with a chelator, followed by reversal of any inhibition by adding excess metal.<sup>26</sup> If excess zinc doesn't reverse the inhibition, it may be due to the fact that zinc can inhibit the zinc enzyme. A considerable amount of anecdotal information exists that zinc inhibits zinc enzymes but how it accomplishes it is not well established. The most thorough study of its mechanism of inhibition is on CPD A.<sup>30,31</sup>

A combination of steady-state and presteady state kinetic and spectral and chemical modification studies led to a mechanistic scheme in which inhibition occurs through the binding of the zinc-monohydroxide species to the active EH species of the enzyme (Scheme 2).<sup>2</sup> The pH independent constant for the inhibition by zinc is 0.71  $\mu$ M. The derived  $pK_a$  of 6 for the inhibition studies agrees with the corresponding value obtained in peptide hydrolysis experiments for the group,  $EH_2$ , whose ionization leads to formation of the catalytically active form of the enzyme.

The ionizable ligand,  $EH_2$ , is assigned to Glu270, since chemical modification of this residue with CMC (1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide) decreases the binding affinity of carboxypeptidase A for zinc and lead by more than 60- and 200-fold, respectively.<sup>31</sup> A bridging interaction between the Glu270-coordinated zinc hydroxide is implicated by the ability of Zn and Pb to induce a marked increase in the visible absorption spectrum of the cobalt enzyme within 20 ms of mixing  $10^{-4}$  M Zn or Pb with  $10^{-4}$  M cobalt enzyme.<sup>31</sup>

Based on the spectro-kinetic and chemical modification studies, a binding mode for the inhibitory zinc ion was proposed to account for its inhibition (Figure 9).<sup>30</sup> The zinc-monohydroxide ion binds to the ionized carboxylate of Glu270 and displaces the zinc-bound water. The inhibitory zinc bridging interaction explains both the loss of metal binding upon chemical modification of Glu270 or lowering pH as well as the increase in absorbance in the cobalt enzyme upon binding lead or a zinc ion. Removal of the Glu270 carboxylate through protonation or chemical modification should decrease inhibitory metal binding. Replacement of the catalytic cobalt-bound water molecule with the hydroxide anion should lead to an increase in visible absorbance (as is observed when azide binds to the metal). A water molecule and a chloride anion complete the zinc inhibitory site since chloride enhances the inhibition by zinc and lead. The  $K_i$  values for the charge-neutral  $Zn(OH)Cl$  and  $Pb(OH)Cl$  are both about  $5 \times 10^{-7}$  M.<sup>30</sup> If the inhibitory

Scheme 2

Figure 9 Schematic of inhibitory zinc-binding site in carboxypeptidase A

metal-monohydroxide complex is charge-neutralized by a multidentate ligand that can bind to other active-site residues, an even lower inhibition constant can be anticipated. Such inhibitory complexes could be very important to regulatory processes and/or toxicological processes involving Pb or other heavy metals with zinc enzymes.

This mode of zinc inhibition is confirmed in its entirety by two different crystallography studies of carboxypeptidase A.<sup>32,33</sup> A 1.7 Å structure of the crystalline carboxypeptidase A that was dialyzed versus 0.33 mM ZnCl<sub>2</sub> reveals a second zinc bound in a distorted tetrahedron composed of the carboxylate of Glu270, a water molecule, a chloride ion and a hydroxide ion.<sup>32</sup> The hydroxide forms a 114° angular bridge between the inhibitory and the catalytic zinc ions. The inhibitory zinc holds the hydroxide at the same location as the catalytic zinc-bound water molecule in the uninhibited enzyme. Superposition of the benzylsuccinate inhibitory complex on the ZnOH<sup>+</sup> inhibited complex demonstrates that the carbonyl group of the inhibitor and the inhibitory zinc ion are almost the same indicating the second zinc ion should interfere with proper positioning of the substrate.<sup>32</sup> This is consistent with the competitive inhibition observed with both zinc and lead.<sup>30</sup>

A similar type inhibitory zinc-binding site is observed in crystals of thermolysin.<sup>34</sup> The features have been compared to those for carboxypeptidase A.<sup>32</sup> The inhibitory zinc to catalytic zinc distance is 3.2 Å for thermolysin and 3.3 Å for

carboxypeptidase A. A water/hydroxide bridges the two sites with a similar geometry, 116° in thermolysin and 114° in carboxypeptidase A. In thermolysin, the coordination sphere is completed by Tyr157, His231 and one of the carboxylate oxygens of Glu166. The latter is particularly interesting since it is the third ligand to the catalytic zinc as well. This inhibitor site therefore resembles the cocatalytic sites seen in many hydrolytic enzymes (Table 3). It therefore means the structural detection of multiple metal-binding sites should always be accompanied with functional studies to discern whether the metal site is active or inhibitory.

This type of inhibitory zinc binding is also observed in other zinc enzymes. The zinc-dependent UDP-3-O-acyl-N-acetylglucosamine deacetylase (LpxC) catalyzes the first committed step in the biosynthesis of lipid A, the hydrophobic anchor of lipopolysaccharide (LPS) that constitutes the outermost monolayer of gram-negative bacteria.<sup>35,36</sup> The catalytic zinc is bound to the NE2 nitrogens of His79 and His242, and an oxygen of the carboxyl group of Asp238 (Table 1).<sup>35,36</sup> (Note the spacing of the first amino acids differs in these studies owing to the numbers given). Mutation of Glu78 to Ala removes zinc inhibition of the enzyme.<sup>36</sup> Based on this finding and the earlier studies of carboxypeptidase A,<sup>30–32</sup> the authors proposed the inhibitory zinc bridges to the catalytic zinc by a water/hydroxide ion. Addition of excess zinc to the crystalline enzyme leads to the observation of two

Table 3 Cocatalytic zinc sites<sup>d</sup>

<sup>a</sup>The amino acid residue that bridges the two-metal sites is shown in *italic bold face*. When the symbol H<sub>2</sub>O is given this may represent from one to three metal-bound water molecules. R is the distance between the metal atoms. When Trp is listed as a ligand, the α-amino and a amide carbonyl are the ligands. See footnote of Table 1 for the definitions of other terms.

zinc ions bound in the active site in much the same fashion as is observed in the metalloproteases discussed above.<sup>35</sup> The postulated inhibitory zinc ion binds 3.4 Å from the catalytic zinc (pdb 1P42). The second zinc binds in a tetrahedral coordination geometry to a solvent molecule, the NE2 nitrogen of His265, and an oxygen from the carboxyl groups of Glu78 and the fatty acid inhibitor, myristic acid.<sup>36</sup> The binding of the inhibitory zinc to the carboxylate of the myristic acid is reminiscent of the binding of similar inhibitory complexes in carboxypeptidase A.<sup>31</sup> The invariant residues, Glu 78 and His265, of the enzyme LpxC are believed to play the same roles in catalysis as Glu166 and His231 do in thermolysin on the basis of the structure of the inhibitory zinc site.

Examination of the crystals of yeast cytosine deaminase shows a second zinc ion coordinated to the active site by a bridging water/hydroxide ion to the catalytic zinc ion. This zinc ion has three other water molecules bound to it some of which have very short (~1.8 Å) bonds to the second zinc.<sup>37</sup> This may represent an inhibitory zinc ion that has bound to the protein with more than one hydroxide ion coordinated to the zinc.

Zinc also inhibits a variety of nonmetalloenzymes.<sup>3</sup> Inhibition constants in the nM range are observed in some cases. In these situations it is possible that the zinc could be involved in regulating the activity of the enzyme. Thionein has been demonstrated to reverse the inhibition glyceraldehyde-3-phosphate dehydrogenase by zinc ions, suggesting the possibility that thionein (apo-metallothionien; see *Metallothioneins*) can be involved in a regulatory capacity with zinc as its partner.<sup>38</sup>

The fact that zinc inhibits enzymes has also been used to design new serine protease inhibitors.<sup>39,40</sup> The type of zinc ligand is important to the inhibition. Thus the zinc-bound bis(5-amidino-2-benzimidazolyl)methane, BABIM, and derivatives of it inhibit several human serine proteases with an inhibition constant of 1 to 25 nM. Zinc increases the inhibition by the agent up to 10 000 times. For example, the  $K_i$  for BABIM inhibition of trypsin decreases from 19 µM to 5 nM in the presence of 100 nM zinc ions at pH 8.2.<sup>39</sup> The crystal structure of trypsin cocrystallized with BABIM and zinc shows zinc tetrahedrally coordinated to two nitrogens of BABIM and two of the catalytic triad residues, His57 and Ser195. This type of zinc-binding site is quite similar to that observed for the inhibition of zinc proteases by zinc ions. Thus, the inhibitory zinc is bridging two catalytic components His57 and Ser195 for trypsin and Glu270 and a zinc-bound hydroxide for carboxypeptidase A. In these enzymes, the zinc hydroxide and serine oxide are the nucleophiles and the glutamate carboxyl group and His imidazole are the general acid/base catalysts. Prostate specific antigen, PSA, or prostate kallikrein is a serine protease that is inhibited by zinc and mercury ions.<sup>41</sup> One of the three zinc-binding sites in the crystalline enzyme is to Asp91, His101 and His234 and a water molecule. It has been postulated that zinc binding could distort the catalytic

triad through minor movements of His101 since it is next to catalytic triad residue Asp102.

### 3.3 Specific Zinc Enzymes

The large number of this class of enzymes makes it difficult to cover the properties of each specific member in any detail. Many have been commented on in other general reviews on this class of enzymes.<sup>3,4</sup> However, some brief comments will be made on some newer members.

#### 3.3.1 Alcohol Dehydrogenases

The ligand nature of the catalytic zinc site varies considerably for the overall grouping of the dehydrogenases but is quite constant for the subfamilies (Table 1). The dimeric mammalian ADHs are NADH-dependent and have two Cys and one His as ligands to a catalytic zinc site (Table 1). The crystal structures of several tetrameric bacterial ADHs have been reported recently. The medium chain alcohol dehydrogenases from thermostable *Thermoanaerobacter brockii*, TBADH,<sup>42,43</sup> originally isolated from a Yellowstone Park hot spring, its mesophilic counterpart *Clostridium beijerinckii*, CBADH,<sup>44</sup> and the archaeon ADH from *Aeropyrum pernix*<sup>45</sup> are all NADP(H) dependent while the archaeon SsADH from *Sulfolobus solfataricus*<sup>46</sup> is NADH-dependent. The catalytic zinc sites of the former NADP(H)-dependent enzymes all have the Cys and His ligands separated by a spacer of 21 to 24 amino acids similar to other ADHs (Table 1). They differ in that the third ligand is now an Asp residue rather than a Cys. All have water as the fourth ligand.

The catalytic zinc site of the NADH-dependent archaeon SsADH is closer to the dimeric ADHs in that it has a Cys as its third ligand. The presumed fourth ligand water is not found, however. The Glu residue next to the second His ligand is now bound to the zinc.<sup>46</sup> The carboxylate oxygens of the equivalent Glu residue in the other tetrameric ADHs are 4 to 7 Å removed from the zinc (pdb files 1KEV, 1H2B, 1YKF). In CBADH this Glu residue is a zinc ligand in the Nicotinamide adenine dinucleotide phosphate (NADP)-free form of the enzyme.<sup>42</sup> However, the distance between the carboxylate oxygen and the zinc increases from 2.35 to 3.94 Å upon binding the coenzyme. In the human  $\chi\chi$  alcohol dehydrogenase, ADH, the equivalent residue, Glu68 is observed 2.9 Å and 2.0 Å from the catalytic zinc in the A and B subunits respectively.<sup>47</sup> In other human and horse ADHs, the carboxylate oxygens are at least 4.7 Å from the catalytic zinc atom. The binding of the Glu to the zinc in this case may be a reflection of the involvement of Glu68 in the displacement of water in a late step-in catalysis as predicted by molecular dynamics calculations.<sup>47,48</sup>

#### 3.3.2 Sorbitol Dehydrogenases

The Glu residue that is sometimes seen as a ligand in the ADHs is also a ligand in some of the structures of the

sorbitol dehydrogenases (SDH) (Table 1). This enzyme and aldose reductase form the polyol pathway that interconverts glucose and fructose. Overproduction of the coenzyme NADH by SDH may play a role in diabetes-induced dysfunction in sensitive tissues.<sup>49</sup> Human SDH is a tetramer that has a catalytic zinc coordinated by Cys44, His69, Glu70 and a water molecule in both the apo and NAD<sup>+</sup> complex.<sup>49</sup> The inhibitor CP-162,572 coordinates the zinc through the N1 nitrogen of its pyrimidine ring and an oxygen of its hydroxymethyl substituent causing the dissociation of Glu70. The inhibitor forms hydrophobic interactions to NADH and likely sterically occludes substrate binding.

The silverleaf whitefly, *Bemisia argentifolii* ketose reductase (BaKR), is tetrameric, with the monomer having a very similar fold to the alcohol dehydrogenases (ADHs).<sup>50</sup> The catalytic zinc ion is tetrahedrally coordinated to Cys41, His66, Glu67, and a water molecule in the enzyme form lacking its coenzyme NADP(H) as is seen in the hSDH. The residue equivalent to the third Asp ligand in the tetrameric ADHs is Glu152 in BaKR. The carboxylate of this residue hydrogen bonds the zinc-bound water. Glu152 has been reported to be the third ligand in rat SDH in place of the Glu67 observed in hSDH and BaKR.<sup>51</sup>

The sequence of *Bacillus stearothermophilus* glycerol dehydrogenase (GlyDH) indicates that it is a member of the third grouping of ADHs, the so-called iron-containing alcohol dehydrogenase family. However it has a strict dependence on zinc for activity.<sup>52</sup> It catalyzes the oxidation of glycerol to dihydroxyacetone (1,3-dihydroxypropanone) with concomitant reduction of NAD<sup>+</sup> to NADH. The catalytic zinc is bound to the NE2 nitrogens of His274 and His256, an oxygen of the carboxylate of Asp173 and a water molecule.<sup>52</sup> The ligand nature of the catalytic zinc site is similar to the tetrameric ADHs but the first cysteine ligand is now replaced by a histidine (Table 1).

### 3.3.3 Hydrolases

This is the largest class of zinc enzymes. The detailed description of the properties of just the metalloprotease group is a major section of a new handbook of proteases.<sup>53</sup> This perspective will therefore only highlight the results of a few novel findings in recent 3-dimensional structures.

Angiotensin-converting enzyme (ACE) plays a critical role in cardiovascular function by catalyzing the cleavage of the carboxy-terminal His-Leu dipeptide from angiotensin I to produce a potent vasopressor octapeptide, angiotensin II. Inhibitors of hypertension were designed in the 1970s on the basis of an assumed mechanistic homology with carboxypeptidase A. Such inhibitors are a first line of therapy for hypertension, heart failure, myocardial infarction, and diabetic nephropathy.<sup>54</sup> Much effort has been put into obtaining a crystalline structure of the enzyme. However, this was not accomplished until very recently when the X-ray structure of human testicular ACE and its complex with one of

the most widely used inhibitors, lisinopril (N2-[(S)-1-carboxy-3-phenylpropyl]-L-lysyl-L-proline; also known as Prinivil or Zestril) was reported at 2.0 Å resolution.<sup>54</sup> Analysis of the three-dimensional structure of ACE shows that it bears little similarity to that of carboxypeptidase A, but instead resembles neurolysin<sup>55</sup> and *Pyrococcus furiosus* carboxypeptidase<sup>56</sup> zinc metalloproteases that have little sequence similarity to ACE. The active site of testicular ACE corresponds to the C-terminal domain of somatic ACE.<sup>57</sup> The somatic ACE contains active sites in its C- and N-terminal domains, which presents new opportunities in drug design.<sup>58</sup>

Mycothiols (1-D-myo-inosityl 2-(N-acetyl-L-cysteinyl) amido-2-deoxy- $\alpha$ -D-glucopyranoside, MSH or AcCys-GlcN-inositol (Ins)) is the major reducing agent in actinomycetes, including *Mycobacterium tuberculosis*.<sup>59</sup> The biosynthesis of MSH involves a zinc-dependent deacetylase, MshB, that removes the acetyl group from the precursor GlcNAc-Ins to yield GlcN-Ins. The 3-dimensional structure reveals a protein that folds in a manner resembling lactate dehydrogenase in the N-terminal domain. The catalytic zinc-binding site is in the N-terminal domain occupying a position equivalent to that of the NAD<sup>+</sup> coenzyme of lactate dehydrogenase. The zinc ion binds to the ND1 nitrogen of His13, the NE2 nitrogen of His147, a carboxylate oxygen of Asp16 and two water molecules. One of the waters is hydrogen-bonded to Asp15. This residue would therefore be in the position of the Glu residues believed to be the general acid/base catalyst in many metalloproteases. This would be the first instance in a metallohydrolase where an Asp residue would be the acid/base catalyst. In addition to the zinc providing electrophilic assistance by allowing substrate to displace the second water molecule, the imidazole of His144 is in a position to form a hydrogen bond to the oxyanion of the tetrahedral intermediate.<sup>59</sup>

The deamination mechanism of *E. coli* cytidine deaminase (CDA) is believed to be similar to that of *E. coli* adenosine deaminase (ADA).<sup>60,61</sup> However, the zinc-binding site of the ADA contains 3 His residues while that of CDA contains two Cys and one His residue (Table 1). Examination of the structures of transition state analogs show that the inhibitor complex is stabilized by a zinc hydroxide and an adjacent carboxyl group of an Asp or Glu residue in the active site. The differences in zinc ligands and tertiary structures of the dimeric ADA and CDA have led to the proposal that the common features in the transition state stabilization have arisen from convergent evolution.<sup>60</sup> The variation in the zinc-binding site in this functional class of enzymes is also evident in the tetrameric *Bacillus subtilis* cytidine deaminase that has three Cys ligands, Cys89, Cys86, and Cys53<sup>62</sup> in agreement with sequence alignment that led to the proposal of the three Cys ligands.<sup>63</sup>

### 3.3.4 $\beta$ -Carbonic Anhydrases

The  $\beta$ -class of carbonic anhydrases includes CAs from plants, algae, bacteria, and archaea.<sup>64,65</sup> The higher plant and

unicellular green algae use the  $\beta$ -CAs for photosynthetic  $\text{CO}_2$  fixation. The three-dimensional structures *Pisum sativum*  $\beta$ -CA,<sup>66</sup> *Porphyridium purpureum*  $\beta$ -CA,<sup>67</sup> and *Methanosarcina thermophila*  $\beta$ -CA<sup>68</sup> show that this group of carbonic anhydrases has a strikingly different catalytic zinc coordination site from the mammalian class (Table 1). In all cases, the catalytic zinc is coordinated by two Cys and a His as was anticipated by XAFS studies of the spinach CA.<sup>69,70</sup> Two of the ligands, His87 (NE2) and Cys90, are supplied by a loop region and a  $\beta$ -sheet, respectively and are separated by a short spacer of two (Table 1). The third ligand, Cys32 (*M. thermophila*  $\beta$ -CA numbering), is supplied by a  $\beta$ -sheet from the N-terminal side. The structure reported for the *P. purpureum*  $\beta$ -CA<sup>67</sup> has an additional Asp coordinated to the zinc and no bound water molecules. On the basis of this structure, it was proposed that this  $\beta$ -CA and possibly the  $\gamma$ -class of CAs do not use a zinc hydroxide mechanism in their function.<sup>67</sup> However, in the other two reported structures the fourth ligand is a solvent molecule (acetate) for *P. sativum*  $\beta$ -CA<sup>66</sup> and a water molecule for *M. thermophila*  $\beta$ -CA.<sup>68</sup> The putative Asp ligand exists in all three enzymes in a highly conserved loop region C-terminal to the third Cys ligand (CysXAspSerArg). In the enzymes in which the Asp is not a ligand, the Arg guanidinium group is hydrogen-bonded to the Asp carboxyl group preventing it from coordinating the zinc.<sup>68</sup> The zinc-coordinated water molecule in the *M. thermophila*  $\beta$ -CA has therefore been displaced by either an acetate carboxylate in the *P. sativum*  $\beta$ -CA or the carboxylate of Asp151 in the *P. purpureum*  $\beta$ -CA. Further studies will be needed to determine what is the function of the Asp residue in question. However, comparison of the  $\alpha$ - and  $\beta$ -CA catalytic zinc sites is of interest in this regard. The positive charge on the zinc in the  $\beta$ -CAs should be reduced by the replacement of two His imidazole ligands by Cys sulfur ligands. The ionization of the zinc-bound water molecule might therefore need the assistance of a neighboring carboxyl group as is postulated in metalloproteases.<sup>2,20,71</sup> A role for Asp151 in catalysis rather than zinc binding could be inferred from the results of a mutation of this residue to an Asn in spinach  $\beta$ -CA.<sup>72</sup> The resulting enzyme still binds zinc but retains little  $\text{CO}_2$  hydratase activity.

The  $\gamma$ -class of CAs has one structural representative from *Methanosarcina thermophila*.<sup>73,74</sup> While it retains three His ligands as in the  $\alpha$ -class, the spacing characteristics change (Table 1). The resulting trimeric enzyme forms a zinc site from the interface of its subunits (see 6.1.2 and Table 5).

### 3.4 Mechanisms of Zinc Enzymes Containing Catalytic Zinc Sites

A number of representatives from the enzymes containing catalytic zinc sites have been extensively studied by both functional and structural means. This group of zinc sites is too large for this perspective to do justice to this voluminous body of work on so many enzymes. However, there are

several recent sources of information on the properties of these enzymes and their mechanism of action. The Handbooks on Metalloproteins<sup>75,76</sup> are particularly good sources for a number of the zinc enzymes having catalytic zinc sites. The large class of metalloproteases is extensively covered in the Handbook of Proteolytic Enzymes,<sup>53</sup> including a separate chapter on their mechanism of action.<sup>20</sup>

## 4 COCATALYTIC ZINC SITES

Cocatalytic zinc sites occur in metalloenzymes where two or three metals are closely spaced to bring about catalysis. There are over five dozen representatives of this type of zinc site with the great majority belonging to the Class III hydrolases (Table 3). The fact that many zinc enzymes required more than one metal for full activity was known for many years. However, the location of these metals relative to one another was often in debate. Prior to structural analyses these metal atoms were often referred to as a combination of a catalytic zinc site and a 'modulating' or 'regulatory' zinc.<sup>77</sup> The metal can usually be removed from a catalytic zinc site without a major effect on the structure of the protein. However, cocatalytic metal sites are often formed from ligands that extend over a large portion of the protein structure. It is therefore not unreasonable that enzymes containing two or more metals in the absence of a structure have been described as having one catalytic metal and a second metal that has structural and/or regulatory effects on activity. Thus far, three-dimensional structures of these enzymes show the metals are always in close proximity.

The alkaline phosphatase family contains three metals in the active site while the rest of the cocatalytic zinc sites contain two metals (Figure 10) (Table 3). Some of these sites contain metals such as copper, iron, and magnesium in combination with zinc. Combinations of Cu(II)/Zn are seen in the superoxide dismutase (SOD) family (see **Copper Proteins with Type 2 Sites**), Zn/Mg are seen in alkaline phosphatase family and lens aminopeptidase, and Fe(III)/Zn in the purple acid phosphatase family.

The bridging of two of the metal sites by a side-chain moiety of a single amino acid residue, usually Asp, and sometimes a water molecule is a novel characteristic of these sites.<sup>6</sup> In principle, any  $\text{sp}^2$  center containing two nucleophilic atoms should have a bridging potential. Thus, the carboxylate oxygens of Asp or Glu, or of a carboxylated lysine, LysCO-2, or the ring nitrogens of the imidazole group of His are found to bridge such sites. This bridging interaction of the amino acid requires the metals to be in close proximity to each other. The distance between the metals in these sites depends on the bridging amino acid. In the case of an Asp, Glu, or LysCO-2 carboxylate, it is generally between 3 and 4 Å (Table 3). In the case of a His imidazole group the distance increases to about 6 Å.

**Figure 10** Schematics of three-metal cocatalytic sites (a) represented by *E. coli* alkaline phosphatase,<sup>78</sup> and two-metal cocatalytic sites (b) represented by *Aeromonas proteolytic* amino peptidase.<sup>79</sup> The one-letter codes D, E, and H are given for the amino acids Asp, Glu, and His respectively

Asp and His predominate as ligands in cocatalytic zinc sites where the frequency is  $\text{Asp} \simeq \text{His} > \text{Glu}$ . These sites also occasionally contain unusual zinc ligands such as amide carbonyls provided by Asn, Gln, and the peptide backbone; hydroxyl groups from Ser, Thr, and Tyr and the amine nitrogen of Lys or the N-terminal amino group of the protein. Perhaps remarkable is the low utilization Cys ligands in these metal sites. Since the ligands to cocatalytic zinc sites often come from nearly the entire length of the protein, the metals may be also important to the overall fold of the protein as well as catalytic function. The secondary structure of the protein plays a major role in providing the ligands to these sites. Some of the families use almost exclusively  $\beta$ -sheets to provide the ligands while other families use all  $\alpha$ -helices (Table 3). In many cases ligands are provided by amino acids residing 1 or 2 residues before or after a  $\beta$ -sheet or an  $\alpha$ -helix. The zinc ions are often pentacoordinate and arranged in a trigonal-bipyramidal geometry.

#### 4.1 Mechanism of Cocatalytic Enzymes

The bridging amino acids and H<sub>2</sub>O likely have critical roles in catalysis. Thus, their dissociation from either metal atom during catalysis will change the charge on the metal promoting its action as a Lewis acid or allowing interaction with an electronegative atom of the substrate. In addition, a released bridging ligand can participate transiently in the reaction as a nucleophile or general acid/base catalyst. The

flexibility of the arm supplying the bridging ligands (e.g. one carbon, C, for Asp and His, 2 C for Glu or 5 C/N for LysCO-2) would be expected to influence the stability and reactivity of the two-metal sites. Thus, it can be envisioned for cocatalytic sites in hydrolytic enzymes that substrate binding involves one zinc site acting as a template for substrate binding while the other zinc provides hydroxide for nucleophilic attack on the  $\text{sp}^2$  center of the ester or amide bond of the substrate. In the next step the roles of the metals can be reversed. In this manner, the metal atoms and their associated ligands play specific roles in each step of the reaction that works to bring about catalysis. The ligands in these sites, in particular, the histidines, are often involved in further hydrogen-bonding interactions with other amino acids. These interactions should effect the charge on the metal and the stability of the metal complex thus fine tuning catalysis and the stability of the metal sites.<sup>3,20</sup>

The reader is referred to the following sources of further information on the specific cocatalytic enzymes: superoxide dismutase,<sup>80</sup> and the reduced form,<sup>81</sup> alkaline phosphatases,<sup>78,82</sup> nuclease P1,<sup>83</sup> purple acid phosphatase,<sup>84,85</sup> amidohydrolase,<sup>86,87</sup> leucine aminopeptidase,<sup>88</sup> general comments on the mechanisms of the phosphatases<sup>89</sup> and aminopeptidases,<sup>89,90</sup> and other cocatalytic zinc enzymes.<sup>76</sup>

## 5 STRUCTURAL ZINC SITES

The early structural studies of metalloenzymes led to the suggestion that metal atoms that have a catalytic role would be composed of ligands from different parts of the polypeptide chain whereas ligands to metal atoms in structural sites would be close together. We now know that both types of zinc sites generally contain at least two ligands that are separated by a short spacer.<sup>4,91</sup> In addition, while many structural zinc sites are composed of ligands from a relatively short sequence in the protein, this is not always the case as might be anticipated from inspection of disulfide structural elements that often come from vastly separated regions of the protein primary structure.

The role of structural zinc sites is likely two-fold. They maintain the structure of the protein in the immediate vicinity of the metal site. In this manner it may influence enzymatic activity by providing active-site residues involved in catalysis and/or effecting the chemical environment of catalytic groups through interaction with amino acids originating from within its metal-binding spacers. However, in many cases, these metal sites also effect the overall stability of the protein as judged by temperature and pH criteria.

While zinc can readily form four-, five-, and six-coordinate complexes, structural zinc sites in proteins have 4 protein ligands and no bound water molecule. This type of coordination is also observed in many of the *Protein Interface* zinc sites.<sup>3,4</sup> The first zinc enzymes recognized to have a

**Figure 11** Schematic of the four-coordinate zinc sites observed thus far in terms of the type of bound ligands. The one-letter codes C, D, E and H are given for the amino acids Cys, Asp, Glu, and His, respectively

structural zinc site were horse liver alcohol dehydrogenase, ADH,<sup>92</sup> and the regulatory subunit of *E. coli* aspartate carbamoyltransferase.<sup>93</sup> In both cases the zinc is bound to four cysteines in a relatively short linear sequence of 15 to 33 amino acids, respectively. There are today more than eleven dozen structural zinc sites with representatives in all six enzyme classes defined by the International Union of Biochemists. The ligands to these metal sites are provided by protein sequences as small as 10 amino acids and as large as 212 amino acids but the majority fall within the range of 15 to 40 amino acids (Table 4). There is nearly always one short spacer separating two amino acids in these sites. The ligands are frequently supplied from within or just before or after a  $\beta$ -sheet secondary structure. Several ligands are supplied by a short amino acid sequence of 3 to 6 amino acids (loop) between two peptide regions of regular ( $\beta$ -sheet or  $\alpha$ -helical) secondary structure. The majority of these loop regions are composed of two  $\beta$ -sheets. While the sulfur of a Cys is by far the preferred ligand for such sites, it is also found in combination with an imidazole nitrogen of His, and/or a carboxylate oxygen from Asp or Glu. The second most prevalent ligand is histidine.

The presence of His and/or Cys in the same zinc-binding site frequently gets some form of a 'zinc-finger' nomenclature (see *Technetium: Organometallic Chemistry*). Based on only 'loose' criteria, some of the sites listed here are still referred to as zinc-finger domains,<sup>94</sup> even if they do not fit the criteria of having DNA-binding properties and/or the ligand nature (2His/2Cys), sequence length ( $\sim 30$  amino acids) and presence of both  $\alpha$ -helix and  $\beta$ -sheets in the zinc-binding site associated with a classical zinc finger.<sup>95</sup> Several reviews exist on the expansion of this nomenclature in the area of zinc protein

sites interacting with nucleic acids (see *Zinc: DNA-binding Proteins*).<sup>96–100</sup>

The expansion of this nomenclature thus far deals mainly with the type of secondary structure present in combination with Cys and His ligands. However, even if one considers only the four main amino acid ligand donors, Cys, His, Asp and Glu, there are 22 permutations of a zinc bound to these four ligands, 12 of which have been observed in zinc enzymes and zinc proteins (Figure 11, Tables 4–6). Several other features of the site can also be important to the resulting influence of the zinc ion. These include the type of secondary structure, outer shell interactions, how many short spacers occur and the order of the ligand donors. This is likely the reason for the frequent use of the word novel in describing new zinc-binding sites owing to the difficulty in classifying the site in terms of the relatively small number of proposed names such as zinc-box, -bundle, -cluster, -finger, -knuckle, ribbon, -ring, etc. The one feature they have in common is the presence of four protein ligands and no coordinated water molecule.<sup>4,5,91</sup>

### 5.1 Structural Sites Involved in Function

Some of these sites can effect function in zinc proteins as well as stabilizing structure. The hydrolase class of zinc enzymes are good examples of this action.<sup>91</sup> In this case, one or more amino acid residues within the active site may be provided by the amino acid spacers between zinc ligands (Figure 12). The side chain of these amino acids may be involved in substrate binding, bond cleavage or modulating the chemical environment of the active site. In addition, other active-site residues are often provided by

**Figure 12** Schematic of a structural zinc-binding site that provides active-site residues from amino acids located within the metal-coordination spacers. Other active-site residues are often provided by the peptide sequence N-terminal to the structural zinc site. The symbol Y can represent more than one amino acid. (Table 4)

the peptide sequence N-terminal to the structural zinc site. Some structural zinc sites that exert influence on function are given below.

#### 5.1.1 Formamidopyrimidine-DNA Glycosylase Family

The bacterial formamidopyrimidine-DNA glycosylase (alias Fpg or MutM) is a bifunctional base-repair enzyme (DNA glycosylase/AP lyase) that removes a wide range of oxidized purines from oxidatively damaged DNA.<sup>101</sup> The crystal structures of the Fpg (MutM) enzymes from *Thermus thermophilus*,<sup>102</sup> *Lactococcus lactis*,<sup>101</sup> *Escherichia coli*,<sup>103</sup> *Bacillus stearothermophilus*<sup>104</sup> and the sequence similar endonuclease VIII (Nei) from *E. coli*,<sup>105</sup> all share the same type of structural zinc-binding site at the end of the C-terminus of the proteins. This zinc site is composed of four cysteine sulfur ligands (Table 4). The first three cysteines are supplied by two  $\beta$ -sheets. The zinc site influences the function of the enzyme through an amino acid located within its metal-binding spacer. The guanidinium group of an Arg residue from within the large central coordination spacer makes two H-bonds with the  $p^{-1}$  and  $p^0$  phosphates of the pyrimidine cleavage site of the substrate. In addition, several other binding interactions come from the N-terminal side of the zinc-binding site.

#### 5.1.2 Rhinovirus-2 Proteinase

The human 2A proteinase from the common cold (rhinovirus) is structurally related to the cysteine proteases.<sup>106</sup> Its active site contains a characteristic catalytic AspHisCys triad. This proteinase also contains a structural zinc-binding site in the N-terminus of the protein composed of Cys52, Cys54, Cys112 and His114 as ligand donors (Table 4). Two  $\beta$ -sheets supply the last three amino acids. The site is believed to be structural since it is not accessible to other ligands and is unlikely to have any functional role in RNA binding.

Chelation and site-directed mutagenesis studies indicate the zinc is essential for formation of an enzymatically active form of the enzyme.<sup>107,108</sup> The zinc-depleted enzyme shows mostly unchanged secondary structure as determined by CD spectroscopy, but not a fully denatured random coil as obtained by the presence of guanidinium hydrochloride.<sup>109</sup> The zinc may therefore be stabilizing a local conformation of the protein that is critical for activity.

This zinc site likely influences enzymatic function through its effect on local conformation. In this case, the crucial catalytic residue Cys106 is supplied from within the large central coordination spacer and the other members of the triad, His14 and Asp35, come from the N-terminal side of the zinc-binding site.

#### 5.1.3 Endonucleases

The enzyme from *Physarum polycephalum* is a homodimer containing two zinc sites per monomer of 324 amino acids.<sup>110</sup> The two zinc sites originate in the N-terminus of the protein spanning residues 41 to 138. The first zinc site is formed from Cys41, Cys100, Cys105 and His110 supplied by three  $\beta$ -sheets while the second zinc uses Cys125, Cys132, His134 and Cys138 as ligands that are supplied from a largely unstructured region of the protein except for one short  $\alpha$ -helix (Table 4). The two zinc ions are separated by 15.3 Å. Both sites contain 3 Cys and 1 His ligand although the order of ligand coordination is different. The second zinc site may play a role in stabilizing the dimer interface since the indole rings of Trp 125 from each monomer are stacked against each other.<sup>110</sup> Neither site is involved in DNA-binding since both are 15 to 17 Å from the substrate complex. However, the active-site His98 amino acid is one residue away from the second Cys ligand in the first zinc site.

#### 5.1.4 Matrix Metalloproteinases

The matrix metalloproteinase (MMP) class of enzymes contain a non-Cys zinc-binding site that has the characteristics of a structural zinc site, that is, four ligands, and no metal-bound water (Table 4). This site contains three His and an Asp residue in a linear sequence spanning 28 amino acids (Table 4).<sup>111,112</sup> The site is highly conserved in the MMPs, occurring in the great majority of sequence-identified MMPs (125/138 sequences in MEROPS 1.7 data set)<sup>113</sup> and has a signature of HX<sub>1</sub>DX<sub>12</sub>HX<sub>12</sub>H. As is likely the case for many structural metal sites, this site may be indirectly effecting the activity of the enzyme. Although this zinc is separated by 12 Å from the catalytic zinc site, the amino acids adjacent to the third and fourth ligands (His) to the 'structural' zinc site provide a number of hydrophobic residues that border the catalytic Glu residue. These regions contain LeuAla and AlaPhe/Tyr sequences on the two sides of one His and an Ala and Phe adjacent to the other His. These residues could provide a hydrophobic environment for the catalytic Glu carboxylate

**Table 4** Structural zinc sites<sup>a</sup>

| Enzyme                                                      | PDB#       | L <sub>1</sub>                    | X  | L <sub>2</sub>     | Y  | L <sub>3</sub>                    | Z  | L <sub>4</sub>       |

group of the MMPs and thus raise its pK<sub>a</sub>, allowing it to play a role in stabilizing the transition state in catalysis.<sup>2</sup> The properties of the structural zinc site in the MMPs and in other similar sites may therefore influence function indirectly through effects on local conformation or local environment.

## 5.2 Zinc Clusters Class II: Histone Lysine Methyl Transferases

Histones undergo extensive posttranslational modifications such as acetylation, phosphorylation, and methylation on their N-terminal peptides that extend out of the nucleosome. Such modifications have been proposed to be part of a histone

code that is recognized by cellular factors that influence gene expression.<sup>114</sup> Some of the SET (Su(var), Enhancer of zeste, Trithorax) domain proteins,<sup>115</sup> in combination with a cofactor S-adenosyl-L-methionine (SAM), are enzymes that methylate lysine 9 of histone H3. These enzymes contain minimally a histone methyltransferase (HMTase) catalytic domain that includes the conserved SET domain flanked by cysteine-rich pre- and post-SET motifs.<sup>116,117</sup> A zinc cluster-type binding site, Zn<sub>3</sub>Cys<sub>9</sub>, is believed to be important to the structural stability of the pre-SET domains of the histone lysine methyl transferases, DIM-5<sup>116</sup> (the gene product of *Neurospora crassa* defective in methylation gene, *dim-5*),<sup>118</sup> and the *Schizosaccharomyces pombe* cryptic loci regulator 4, Clr4.<sup>117</sup> A fourth zinc site has been found in the *Neurospora*

*crassa* Dim-5 enzyme bound to four Cys residues (Table 4).<sup>119</sup> This zinc is 39 to 43 Å from the zinc cluster.

The zinc cluster sites have several features in common with the  $\beta$ -domain three-metal clusters of eukaryotic metallothioneins (see **Metallothioneins**). All of these clusters can be viewed as simple hexagons in two dimensions (Figure 13). The hexagon is composed of alternating zinc ions and bridging Cys ligands. Each zinc has two other nonbridging Cys sulfurs ligated to it. In each case there is a short spacer of 7 amino acids between two of the bridging Cys ligands. However, the spacers to the third bridging Cys are much larger for the histone methyltransferases. This is due to large inserts of 28 and 46 amino acids between the fifth and sixth cysteines in the Clr4 and DIM-5 HMTases, respectively, compared to 1- and 3-amino acid spacers for the human,<sup>120</sup> mouse,<sup>121</sup> and sea urchin<sup>122</sup> metallothioneins, respectively. The spacing characteristics of the last four cysteine ligands in the HMTases is highly conserved compared to that of the first five cysteine ligands. A search using the motif [YFIK]ECX<sub>3</sub>CXCX<sub>3</sub>CX<sub>2</sub>R leads to only 46 proteins, many of which are suspected to be HMTases.<sup>91</sup> The majority of the putative large spacers between the fifth and sixth Cys ligands are between 24 and 29 amino acids while two are 46 and 66 amino acids. The resulting variation in the putative spacing of the first five Cys residues is given by the subscripts in the sequence: CX<sub>1-2</sub>CX<sub>2-6,8</sub>CX<sub>3-7</sub>CX<sub>0-1</sub>C.

**Figure 13** Properties of some zinc cluster sites observed in zinc enzymes and metallothionein. The bridging Cys residues as well as their spacing are identified for (a) *Schizosaccharomyces pombe* Lysine methyltransferase Clr4,<sup>117</sup> (b) *Neurospora crassa* Histone H3 methyltransferase DIM-5,<sup>116</sup> (c)  $\beta$ -domain of human metallothionein-2,<sup>120</sup> and (d)  $\beta$ -domain of sea urchin metallothionein MTA.<sup>122</sup> The PDB numbers are respectively: 1MVH, 1ML9, 1MHU, and 1QJL.

## 6 PROTEIN INTERFACE ZINC SITES

Thus far, we have considered how zinc can directly influence enzyme structure and function through its action in catalytic, cocatalytic, and structural zinc-binding sites formed from intramolecular ligands in monomeric proteins or in a subunit of a multi-subunit protein. However, zinc can also bind to the interface of protein molecules and form all of the zinc-binding sites mentioned above. In this capacity, it may also influence the quaternary structure of proteins. Zinc binding to ligands supplied from protein molecules at their interface contact surface has been observed in increasing numbers in the last few years.<sup>3,4,123</sup> These interactions can lead to dimers or trimers of the same protein or link two different proteins through the intermolecular ligands. The amino acid residues His, Glu, and Asp primarily supply the ligands to these sites but Cys-containing sites are also found (Table 5). The ligands are generally contributed by some form of secondary structure with  $\beta$ -sheets predominating. The most common types of these sites are formed from either each protein molecule providing two zinc ligands or one protein moiety providing three ligands and the second providing one as in the case of the nitric oxide synthase family and superantigens, respectively (Figure 14).

The resulting zinc-binding sites can function as catalytic zinc sites as in  $\gamma$ -carbonic anhydrase<sup>74</sup> or structural-like sites as in the proposed superantigen-MHC class II complexes<sup>124</sup> or cocatalytic-like sites as in the zinc-sensing transcriptional regulator ZntR.<sup>125</sup>

### 6.1 Protein Interface Catalytic Zinc Sites

While one might anticipate the binding of zinc between protein molecules to indirectly effect protein function by a number of means, it is perhaps most remarkable that these interactions can lead to catalytic zinc sites. This can occur even when all of the elements are in each monomer of the enzyme. In other cases, the intermolecular zinc site may be involved in placing the enzyme in the proper physiological place to exercise its function.

**Figure 14** Protein interface zinc sites are formed at the interface of two proteins with generally four amino acid ligands binding to the zinc ion. The most common forms supply (a) two amino acid ligands from both protein moieties or (b) three amino acids ligands from one protein moiety and one ligand from another.

### 6.1.1 $\gamma$ -Carbonic Anhydrase: Trigonal-Bipyramidal Zinc Site

The carbonic anhydrases are classified broadly as  $\alpha$ ,  $\beta$  and  $\gamma$  enzymes. X-ray structures exist for all three forms (Tables 1 and 5). The catalytic zinc sites are highly conserved for each class of enzymes but differ markedly when the classes are compared. The  $\alpha$ -class of enzymes contain two His ligands separated by a short spacer of one, a third His ligand supplied from the C-terminal side of the protein and one water molecule to complete the tetrahedrally bound zinc (Table 1). The  $\beta$ -class of enzymes contain a zinc site formed from a Cys and His ligand separated by 2 amino acids and another Cys ligand supplied from the N-terminal side of the protein (Table 1). The first member of the  $\gamma$ -class of carbonic anhydrases, CAM, was isolated and characterized from the methanogenic archaeon *Methanosarcina thermophila*.<sup>126</sup> Both the  $\alpha$  and  $\gamma$  classes of enzymes have three histidine ligands supplied by  $\beta$ -sheet secondary structures in the catalytic zinc site (Tables 1 and 5). However they differ in the length of their short spacers (one versus four). This in turn allows the second His of the trimeric CAM enzyme to become part of the zinc-binding site in an adjacent monomer rather than bind to its own active-site zinc. The crystal structures of the native zinc enzyme and the cobalt-substituted enzyme show the metal-binding site is formed from His81 (ND1) and His122 (NE2) of one monomer and His117 (NE2) of another monomer.<sup>73,74</sup> In contrast to the tetrahedral zinc site observed in the  $\alpha$ -class of enzymes that have only one zinc-bound water molecule (Table 1), the zinc CAM contains two water molecules in a trigonal-bipyramidal coordination geometry while the cobalt CAM contains three bound waters in an octahedral geometry. Both of these crystalline geometries are consistent with results obtained from XAFS studies performed in the solution state.<sup>127</sup>

### 6.1.2 Human Glyoxalase I: Square Pyramidal and Octahedral Zinc Sites

Another remarkable catalytic zinc site is found in human glyoxalase I where the C-terminal domain of one monomer interacts with the N-terminal domain of a second monomer to form two zinc-binding sites at the interface of the subunits.<sup>128</sup> The active-site zinc is coordinated by four protein residues and one water molecule in a square pyramidal coordination geometry. The base of the pyramid is formed from Gln33 and Glu99 of one subunit, Glu172 from the second subunit and a water molecule. The apex of the pyramid uses His126 from the second subunit. Such a geometry could be viewed as octahedral with one axial ligand missing. The results of EPR (cobalt enzyme)<sup>129</sup> and XAFS (zinc enzyme)<sup>130</sup> studies suggest a distorted octahedral coordination in solution. The sixth ligand site may be a water molecule. Another remarkable feature of this metalloenzyme is that while zinc binds tighter than Mg ( $3 \times 10^{-11}$  vs  $1 \times 10^{-6}$  M) the Mg enzyme is fully active.<sup>131</sup> The octahedral metal-coordination geometry and the

functional replacement of Zn by Mg is unusual for catalytic zinc sites. These results raise the possibility that Mg is the functional metal *in vivo*.

Mutagenic studies of the zinc ligands of the human enzyme suggest that the metal ligand Glu172 may be directly involved in catalysis.<sup>132</sup> Thus, both the E172Q and Q33E/E172Q double mutant still bind zinc but the catalytic activity is decreased by  $10^5$  and  $10^8$  fold, respectively. Crystallographic results of the enzyme complexed with a transition state analog S-(N-hydroxy-N-*p*-iodophenylcarbamoyl)glutathione, HIPC-GSH, that mimics the enediolate intermediate that should form along the reaction pathway are consistent with this hypothesis.<sup>133</sup> In this structure, the two oxygen atoms of the hydroxycarbamoyl moiety displace two zinc-bound water molecules that are observed in a possible product-like complex of S-*p*-nitrobenzyloxycarbonylglutathione, NBC-GSH. In addition the Glu172 carboxylate oxygen-Zn distance has increased from 2.0 Å to 3.3 Å in the HIPC-GSH complex indicating it is no longer a ligand to the zinc. The resulting coordination of the zinc thus changes from square pyramidal in the transition state-like complex to distorted octahedral in the product-like complex. The zinc ion is envisioned to play a Lewis acid role in catalysis by directly coordinating the enediol intermediate and the freed zinc ligand Glu172 is proposed to facilitate proton transfer between the adjacent carbon atoms of the substrate.<sup>133</sup>

### 6.1.3 *E. Coli* Glyoxalase I: Trigonal-Bipyramidal Zinc Site

While the human and *E. coli* enzymes have similar amino acid sequences and three-dimensional structures, they do not have the identical protein ligands. Nickel is believed to be the native metal in the *E. coli* glyoxalase I enzyme (see *Nickel Enzymes & Cofactors*).<sup>134</sup> The nickel is bound octahedrally to His5 (NE2) and Glu56 (OE1) from one monomer, His74 (NE2) and Glu122 (OE1) from the other, and two water molecules.<sup>135</sup> Structure and function studies of *E. coli* glyoxalase I have shown the active nickel, cobalt, and cadmium enzymes have octahedral geometry while the zinc enzyme has trigonal-bipyramidal coordination and is inactive.<sup>135</sup> The zinc coordination site contains four protein ligands plus a single water molecule. In contrast, the metal-coordination sites in the active forms of the enzyme includes two water molecules bound to the metal ion, suggesting that this may be a key feature of the catalytic mechanism.

### 6.1.4 *E. Coli* PdxA: Octahedral Zinc Site

Pyridoxal 5'-phosphate is an essential cofactor for many enzymes responsible for the metabolic conversions of amino acids. The fourth step in its synthetic pathway in *Escherichia coli* is catalyzed by the divalent metal ion-dependent enzyme 4-hydroxythreonine-4-phosphate dehydrogenase (PdxA), which converts 4-hydroxy-L-threonine phosphate (HTP) to 3-amino-2-oxopropyl phosphate.<sup>136</sup> The

enzyme active site is located at its dimer interface, within a cleft between two subdomains and involves residues from both monomers and two zinc ions. Each zinc ion is bound to NE2 nitrogens of His166 and His266 from one monomer and the NE2 nitrogen of His211 of a second monomer and 3 water molecules in an octahedral coordination geometry (Table 5). These histidines are strictly conserved in 74 members of this family of enzymes. The amino and hydroxyl groups of the substrate, HTP, bind to the zinc ion in a pentacoordinate manner by replacing the three water molecules.<sup>136</sup>

#### 6.1.5 *E. Coli* L-histidinol Dehydrogenase: Octahedral Zinc Site

L-histidinol dehydrogenase (HisD) catalyzes the last two steps in the biosynthesis of L-histidine: sequential NAD-dependent oxidations of L-histidinol to L-histidinaldehyde and then to L-histidine.<sup>137</sup> HisD functions as a homodimer and requires the presence of one zinc ion per monomer. The x-ray structure of *E. coli* HisD in the presence of zinc, NAD<sup>+</sup> and the substrate, L-histidinol, shows the zinc bound to the side-chain amide carbonyl of Gln259, the NE2 nitrogen of His262 and Asp360(OD2) of one monomer and the NE2 nitrogen of His419 of the other monomer and the substrate ND1 nitrogen and its amino group in a octahedral coordination geometry.<sup>137</sup> The role of zinc in this case is to position the substrate for catalysis. Since the NE2 nitrogen of His237 is within H-bonding distance of the histidinol OH, it likely participates in acid-base catalysis.

## 6.2 Protein Interface Structural-like Zinc Sites

There are a number of protein interface sites that have the properties of an enzyme structural zinc-binding site in that they are composed of four protein ligands and no water molecules. These sites may be involved in local protein conformation or be involved in stabilizing quaternary structure. The metal ion acting in this manner is not directly involved in the function of the protein but may still play an indirect role in aligning critical components of the protein for its intended function.

### 6.2.1 Zinc-binding Sites in Superantigens

*Streptococcus pyogenes* and *Staphylococcus aureus* secrete a number of enterotoxins and pyrogenic exotoxins, respectively. These toxins are known as superantigens, since they simultaneously form complexes with the major histocompatibility class II (MHC-II) molecules and T-cell receptors (TCRs) enabling them to activate a number of T-cell lymphocytes.<sup>124,138,139</sup> Thus, superantigens stimulate up to 20% of the T cells while only 0.0001% to 0.001% T cells are stimulated upon normal antigen presentation. The massive T-cell activation leads to cytokine release and systemic shock. The staphylococcal enterotoxins (SE) A, B, C1-C3, D and

E, toxic shock syndrome toxin (TSST-1), the streptococcal pyrogenic exotoxins (SPE) A, B, Cs, G, and H, the streptococcal mitogenic exotoxins, SMEZ and SMEZ-2 are the best structurally studied superantigens thus far (Tables 5 and 6).

Zinc is believed to be an important factor in the mechanism of T-cell activation. Thus binding of staphylococcal enterotoxin A and enterotoxin E to HLA-DR1 is completely abolished by low concentrations of Ethylenediaminetetraacetic acid (EDTA).<sup>140</sup> This binding is completely restored by the addition of a 2  $\mu$ M excess of Zn<sup>2+</sup> but not by Ca<sup>2+</sup>, Mg<sup>2+</sup> or other metal ions. Studies using EDTA  $\pm$  ZnCl<sub>2</sub> show zinc-dependent binding of *Streptococcus pyogenes* exotoxin (SPE-C), SPE-G, SPE-H and SMEZ and SMEZ-2 to the MHC class II molecule HLA-DR1 (affinities of 15 to 36 nM).<sup>138</sup> On the basis of these criteria, the superantigens SEB and the toxic shock syndrome toxin TSST do not show zinc-dependent binding to the MHC class II molecule.

Two distinct zinc-binding sites are apparent from the reported structures of the superantigens (Tables 5 and 6). These zinc sites contain at least three protein ligands with each site having short and long spacers. The third ligand comes from the N-terminal side of the second ligand. In one case the short spacer is one (Asp (OD1)-X-His (NE2)) with both ligands coming from a  $\beta$ -sheet, located in the C-terminal side of the protein. The third ligand is either an Asp or His residue located 33 to 39 amino acids away: SEA,<sup>141,142</sup> SEC3,<sup>143</sup> SED,<sup>144</sup> and SEH<sup>145</sup> (partial) and SPE-C,<sup>146</sup> SPE-H, and SMEZ-2<sup>147</sup> all contain this type of zinc-binding site (Tables 5 and 6). The second type of zinc-binding site has a short spacer of 3 and contains two His ligands in the N-terminal side of the superantigen with the third ligand located 27 to 34 amino acids away: SEC2,<sup>148</sup> SEA<sup>149</sup> (2<sup>nd</sup> Zn site) and SPEA and SPEA1<sup>150,151</sup> contain this type of site. The fourth ligand in these sites is quite variable. It may come from a neighboring protein molecule, from within the same molecule or be a bound water molecule. The variability in the fourth ligand could be due to the fact that this ligand should come from the MHC class II molecule. His81 of the  $\beta$  chain of the DR1 molecule has been proposed to be this ligand based on the fact that mutation of this ligand disrupts HLA-DR1 binding to SEA but not SEB or TSST-1 that do not bind zinc strongly.<sup>152</sup>

A somewhat similar zinc-binding site was observed in crystals of rat submaxillary gland tonin that had been grown in a zinc-containing mother liquor.<sup>153</sup> The zinc binds to the NE2 nitrogens of His97, His99, and the catalytic His57 of one molecule and Glu148 of an adjacent one. The presence of zinc was reported to inhibit the enzyme at pH 6.5. The structure of the zinc-binding sites in the dimeric form of psoriasin (S100A7) also contains three His and one Asp ligand.<sup>154</sup> This 22.7 kDa homodimeric protein belongs to the S100 class of calcium-binding EF-hand proteins (*see Calcium-binding Proteins*). Two zinc-binding sites occur per dimer through the formation of a tetrahedral site consisting of the N-terminal

**Table 5** Protein interface zinc sites<sup>a</sup>

<sup>a</sup>See footnote of Table 1 for the definitions of terms.

His17 (NE2) and Asp24 (OD1) of one monomer and His86 (NE2) and His90 (NE2) of the other. This binding site is apparently weak since it is reported to have a dissociation constant of 100 μM.

The finding of zinc binding at the interface of two enterotoxin molecules in several of the superantigens (Table 5) could mean that zinc influences the function by forming dimers of the superantigen. SED crystallizes as a Zn<sup>2+</sup>-dependent dimer with two high affinity zinc sites located between the C-terminal β-sheets of the two monomers.<sup>144</sup> Each zinc is tetrahedrally coordinated by His118 from one SED molecule and Asp182, His220 and Asp222 from the other. Thus, in the case of SED it has been suggested that zinc binding could induce dimer formation and each monomer could bind to the MHC class II molecule.<sup>144</sup> This type of zinc ligation and zinc-mediated dimerization occurs in several SECs, but not in most staphylococcal enterotoxins. The potential importance of zinc in SEC-mediated pathogenesis was investigated by site-directed mutagenesis by replacing the SEC zinc-binding ligands with alanine.<sup>143</sup> The SEC mutants were unable to bind zinc and failed to form dimers. However, it was concluded that zinc binding was not essential for T-cell stimulation, emesis, or lethality although in general the mutants were less pyrogenic.

### 6.2.2 Nitric Oxide Synthase

Although His, Glu, and Asp residues are frequently used in forming these protein interface sites, Cys-containing sites are also observed. A zinc ion is tetrahedrally coordinated to a pair of symmetry-related Cys residues near the bottom of dimer interface of the bovine endothelial nitric oxide synthase, eNOS or NOS-3 (Table 5) (*see Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry*).<sup>155</sup> The Cys ligands, Cys96 and Cys101, are part of a small three-stranded antiparallel β-sheet that orientates the Cys ligands in the same direction directly across the antiparallel strands. The zinc site is further stabilized by H-bonds between the Cys ligands and the backbone amide NH of Leu102 and Gly103 as well as a H-bond of the amide NH of Cys101 to the carbonyl of Asn468. The zinc is positioned equidistant from each heme (21.6 Å) and each tetrahydrobiopterin, H<sub>4</sub>B (12 Å). Ser104, 2 amino acids removed from one of the Cys ligands, H-bonds directly to the pterin side-chain hydroxyl group. The metal center is believed to act in a structural capacity to maintain the integrity of the pterin-binding site. It is also centered in the most electropositive region of eNOS. It could therefore provide a binding site for the electronegative reductase domain. In

addition, if one of the Cys ligands has nucleophilic capacity it could undergo S-nitrosylation.<sup>156</sup> A precedent for this is the DNA repair protein *Escherichia coli* Ada in which a zinc-bound Cys can be methylated irreversibly in the DNA complex.<sup>157</sup> The nitrosylated Cys might then release zinc, which may be controlled by the redox status in situ.<sup>158</sup>

These Cys residues are conserved in 20 mammalian e, i, and n-NOS enzymes, suggesting that the site may occur in all forms of NOS.<sup>155</sup> The crystal structures of the *E. coli* expressed human endothelial, eNOS,<sup>159</sup> the human inducible form iNOS or NOS-2,<sup>159,160</sup> mouse iNOS<sup>161</sup> and the rat neuronal nNOS or NOS-3<sup>162</sup> all have this same zinc-binding site in agreement with the sequence analysis.

### 6.2.3 *Shaw T1*

A highly conserved zinc protein interface Cys/His site occurs in the N-terminal, cytoplasmic tetramerization domain (T1) of voltage-gated K<sup>+</sup> channels.<sup>163</sup> The crystal structure of the *Shaw* T1 tetramers reveals a four-layered protein scaffolding. Within layer 4 on the proposed membrane side of the tetramer, there are 4 zinc ions coordinated by a His and two Cys from one monomer and one Cys from another. The zinc is tetrahedrally coordinated by Cys102 and Cys103 from layer 4 and His75 (ND1) from layer 3 of one monomer and Cys81 from layer 3 of another monomer. This site (CysCysX<sub>20</sub>CysX<sub>5</sub>His of one monomer) is conserved for 62 members of the *Shaw*, *Shab*, and *Shal* T1 domain sequences but not for the *Shaker* T1 domain.<sup>163</sup> The physiological function of this zinc site is unknown.

### 6.2.4 Human Tyrosine Kinase Lck complexes with CD4 and CD8

The Src family tyrosine kinase Lck transduces signals that are required for normal T-cell lymphocyte development and antigen-dependent activation of mature T cells.<sup>164</sup> It does this by associating its N-terminus with the cytoplasmic tails of T-cell coreceptors CD4 and CD8 $\alpha$  in a zinc-dependent manner. The solution structures of ternary zinc-CD4-Lck and zinc-CD8 $\alpha$ -Lck complexes were determined by using peptides of the appropriate regions of the proteins.<sup>164</sup> In each case, zinc binds to Cys23 and Cys29 of Lck and completes its tetrahedral coordination by binding to two Cys residues of CD4 (Cys420 and Cys422) or CD8 $\alpha$  (Cys194 and Cys196). The zinc is thus used to clasp the T-cell receptors to Lck. Other similar structural elements also are observed in this binding process.

### 6.2.5 Zinc-his/Glu Sites at Protein Interfaces

There are several His/Glu combinations that lead to zinc binding at the interface of proteins (Table 5). A number of these zinc sites are symmetry related. Thus zinc binds between Glu139 (OE1) and His178 (NE2) in one molecule of

the asymmetric crystal unit of the 4 phenylimidazole-bound *Sulfolobus solfataricus* cytochrome P450 and their symmetry residues in another molecule.<sup>165</sup> The functional importance of a dimer and zinc's contribution to its stability is not known. However, no zinc was added in the crystalline procedure. A His/Glu site with a short spacer of 3 is observed in the dimer interface of mouse survivin (Table 5).<sup>166</sup> The human survivin does not form a similar intermolecular zinc site.<sup>167</sup>

In crystals of the high molecular weight form of nerve growth factor 7S NGF, a zinc is tetrahedrally bound between His82 (NE2) and Glu75 (OE1) of the  $\alpha$ -subunit and His217 (NE2) and Glu222 (OE1) of the  $\gamma$ -subunit.<sup>168</sup> The binding of zinc to this interface is consistent with the observation that zinc enhances the stability of the 7S complex.

## 6.3 Zinc Sites Induced by High Zinc Concentrations in Crystallization Solutions

Zinc is often used in crystallization buffers because it appears to aid in formation of high quality crystals. Since the zinc concentrations used to obtain the crystals is in the range of a few mM to over 100 mM these sites often may not be of physiological significance. The effect of zinc on protein function and/or structure should be correlated to the concentration needed to observe zinc binding to the crystalline enzyme. However, the fact that zinc has the property of making better protein crystals may reflect its ability to perform inter-protein interactions under physiological conditions where the concentration of water may not be 55 M and the amount of zinc needed for the binding maybe much less. The great majority of these zinc sites use His, Asp, and Glu as ligands.

The human pathogen *Legionella pneumophila*, the etiological agent of the severe and often fatal Legionnaires' disease, produces a major virulence factor, termed macrophage infectivity potentiator protein (Mip), that is necessary for optimal multiplication of the bacteria within human alveolar macrophage.<sup>169</sup> The interaction of the C-terminal FKBP (binds drug FK506) domains of adjacent Mip dimers in the crystal lattice is mediated by two zinc ions, which were added for crystallization and enabled the solving of the structure. The NE2 nitrogen of His205 from one Mip C-terminal domain and Glu164(OE1) from a neighboring molecule and two water molecules one of which bridges to a second zinc ion that binds to Glu130(OE1) of the first Mip molecule and two water molecules complete the tetrahedral coordination of each zinc ion. Zinc is not an intrinsic part of the Mip protein and does not influence the enzyme's peptidylprolyl isomerase activity.<sup>169</sup> The authors reason its sole function is to form the observed crystal contact.

The crystals of the human interferon- $\alpha_{2B}$  dimers, huIFN- $\alpha_{2B}$ , obtained in the presence of 40 mM zinc acetate<sup>170</sup> show the most extensive interactions occur in the vicinity of the zinc-binding site. This site is formed from adjacent Glu residues 41 and 42 located on a  $3_{10}$  helix. A distorted-tetrahedral zinc coordination sphere is completed

by the identical glutamates from a two-fold symmetry-related molecule. However, gel permeation studies indicate huIFN- $\alpha_{2B}$  is a monomer up to 50  $\mu$ M and the presence of 1 mM Zn does not shift the equilibrium toward a dimer.<sup>170</sup>

A tetrahedral zinc-binding site between symmetry-related monomers in the cytochrome C reductase is composed of a His and an Asp ligand in one monomer, a His ligand from the second monomer and a chloride ion.<sup>171</sup> Since there is no known effect of zinc in this system, the site is considered to be an artifact. Five tetrahedral zinc-binding sites are observed in symmetry-related molecules of granzyme B in complex with a peptide analog, AC-IEPD-CHO.<sup>172</sup> These zinc coordination sites are believed to be artifacts of using zinc in the crystallization buffer since zinc is not required for substrate binding.

Zinc (6–10 mM) is used to aid in crystallization of chicken tropomodulin.<sup>173</sup> The resulting crystals contain a zinc-binding site at the interface of two protein molecules in the crystal lattice (Table 5). It is not known what effect zinc has on the protein function in solution. When the crystals of *Urtica dioica* agglutinin isolectin I are grown in 100 mM zinc acetate, the C-terminal domains binds two zinc ions at the sugar binding site.<sup>174</sup> Thus, His47 of one protein molecule and His67 of a second one bind the first zinc while Asp 75 of molecule one and His47 of molecule two bind the second zinc ion. The effect of zinc under more physiological conditions is not known.

## 7 ZINC-BINDING PROTEINS

Structural studies in recent years have revealed a number of zinc-binding sites in proteins of diverse function. In compiling Table 6, a number of DNA-binding proteins have been left out since there are several good sources of information on these zinc sites, which usually contain Cys and His ligands (see **Zinc: DNA-binding Proteins**).<sup>96–100,175,176</sup>

The great majority of these zinc sites are formed from four protein side-chain ligands to yield a tetrahedral binding site. Their function may therefore be related to the local and/or overall structure since the sites span from 22 to 227 amino acids. As in the case of structural zinc sites in enzymes (Table 4), the vast majority of the sites contain at least one short spacer. The residues generally are supplied from  $\beta$ -sheets or reside within one or two residues of such a secondary structure (Table 6). The amino acids, His and Cys, are the predominate suppliers of ligands but several sites are made up of combinations of His, Asp, and Glu residues. Some examples of the group will be highlighted herein since the properties of a number of the listed proteins have been detailed elsewhere.<sup>4</sup>

### 7.1 LIM Domain Proteins

Two consecutive zinc-binding sites spanning 50 to 54 amino acids with the zinc ions located between 16.5 Å and

18.0 Å occurs in a number of proteins of diverse physiological function (Table 6). The zinc-binding sites are often referred to as zinc fingers but they are not involved in DNA-binding and their purpose appears to be a structural one. The name LIM comes from the identification of tandem copies of a Cys-rich motif that was present amino-terminal to the homeodomains in the proteins encoded by the *Caenorhabditis elegans* genes *lin-11*, *isl-1* and *mec-3* (see **Zinc: DNA-binding Proteins**).<sup>177</sup> NMR studies have determined the structural properties of several of the LIM domains (Table 6). These tetrahedral zinc sites contain four protein ligands that are mainly Cys residues in combination with His and Asp residues. The N-terminal zinc site is highly conserved having a zinc signature of CCHC. The C-terminal site is more variable with the last two ligands being various combinations of Cys with His or Asp. No bound water molecules are found in these sites. The first and third ligands usually are supplied from a  $\beta$ -sheet structure. The second ligand resides in a loop region between two  $\beta$ -sheets while the fourth ligand may come from an  $\alpha$ -helix, or  $\beta$ -sheet region of the protein (Table 6).

These domains are often found as repeats in proteins that are involved in diverse biochemical processes. The LIM domains are thought to function as protein interaction modules, mediating specific contacts between members of functional complexes and modulating the activity of some of the constituent proteins.<sup>178</sup> Group 1 of the LIM proteins contain the LIM homeodomain (LHX), LIMK (LIM kinases) and LMO (rhombotin) subfamilies.

LMO2 and LMO4 are members of a small family of nuclear transcriptional regulators that are important for both normal development and disease processes. LMO2 is essential for hemopoiesis and angiogenesis, and inappropriate overexpression of this protein leads to T-cell leukemias.<sup>179</sup> LMO4 is developmentally regulated in the mammary gland and has been implicated in breast oncogenesis.

Group 2 of the LIM domains contains the Cys-rich Proteins (CRP) and Cys-rich Intestinal Protein (CRIP) subfamilies that have tandem repeats of zinc-binding sites containing the ligands CCHC and CCCC (Table 6). The structures of the chicken,<sup>180</sup> quail,<sup>181,182</sup> and rat<sup>183,184</sup> proteins are determined by NMR. These proteins have a role in the contractile machinery of muscle. Three vertebrate CRPs (CRP1-3) are associated with the actin cytoskeleton, and one has been shown to be required for striated muscle structure and function in muscle differentiation and function.<sup>180</sup>

The PINCH (Particularly Interesting New Cys/His rich protein) is a widely expressed adapter protein that contains five LIM domains that belong to group 3 of the LIM domain subfamilies.<sup>185</sup> PINCH is found in focal adhesions, large cellular complexes that link extracellular matrix to the actin cytoskeleton and has been implicated as a platform for multiple protein–protein interactions that mediate integrin signaling within focal adhesions.<sup>186</sup>

## 7.2 BIR Domain Proteins

Another repeating zinc-binding site defines a domain in a protein that is an inhibitor of apoptosis, IAP. Apoptosis is a physiological cell suicide program that is essential to the development and maintenance of healthy tissues.<sup>187</sup> Thus, malfunctioning cells are targeted for destruction. Disruption of this process is implicated in cancer, auto immune, and immunodeficiency diseases. The IAP family members contain a protein segment of about 80 amino acids, named the baculovirus IAP repeat (BIR), domain since it was first observed in apoptosis suppressors in the genome of baculoviruses. BIR domains have been found in mammalian, fly, nematode, yeast and virus proteins.<sup>187</sup> One of the first described members of the family was Survivin, a relatively small 16 kDa protein. Both the human and mouse proteins contain a zinc-binding site in the N-terminal, BIR-like domain.<sup>166,167</sup> The zinc binds to Cys57, Cys60, His77 (NE2) and Cys84 in both human and mouse proteins (Table 6).

The X-ray structures of several of these proteins shows a highly conserved zinc-binding site spanning 28 amino acids with the spacing characteristics of  $Cx_2Cx_{16}Hx_2C$  (Table 6). The first two Cys ligands are supplied by a  $\beta$ -sheet and loop region between two  $\beta$ -sheets, while the third His ligand resides in an  $\alpha$ -helix and the last Cys ligand is in a loop between two  $\alpha$ -helices.

Proteins containing these domains have been shown to inhibit caspases.<sup>187</sup> At least 8 members of the mammalian family of IAP proteins containing two to three copies of the BIR domain have been identified.<sup>188</sup> These BIR domains may function differently in the inhibition of the caspases. The third BIR repeat, BIR3, of the X-linked protein, X-linked inhibitor of apoptosis protein (XIAP) binds to monomeric initiator caspase-9 to form a heterodimer and thus prevents caspase-9 from forming its functional dimer, resulting in loss of enzymatic activity.<sup>188</sup>

The crystal structure of the BIR2 domain of XIAP in complex with caspase-3 reveals the inhibitor makes limited contacts through its BIR domain to the surface of the enzyme, and most contacts to caspase-3 originate from the N-terminal extension.<sup>189</sup> The mechanism of inhibition is likely due to blocking substrate binding.

The mitochondrial protein Smac/DIABLO promotes apoptosis by eliminating the inhibitory effect of IAPs through physical interactions.<sup>190</sup> The crystal structure of Smac/DIABLO complexed with the BIR3 domain of XIAP indicate the relief of inhibition by the IAP protein occurs mainly through the N-terminal four residues (Ala-Val-Pro-Ile) in Smac/DIABLO. The N-terminal Ala binds in a hydrophobic pocket of BIR3, that makes five hydrogen bonds to neighboring residues on BIR3.

The inhibitor of apoptosis protein DIAP1 suppresses Dronc-dependent cell death in *Drosophila melanogaster*, with the second BIR domain (BIR2) playing an important role.<sup>191</sup> DIAP1 is an E3 ubiquitin ligase. The BIR2 domain of DIAP1 recognizes a 12-amino acid residue sequence in Dronc that

is essential for DIAP1 binding to Dronc, and for targeting Dronc for ubiquitination. Three proteins, Reaper, Hid and Grim, (RHG proteins) promote apoptosis in *Drosophila melanogaster* in part by binding to the BIR2 of DIAP1 through their conserved N-terminal sequences in a manner similar to that observed for the Smac and XIAP complex.<sup>192</sup>

Five very similar BIR repeats are observed in the melanoma inhibitor of apoptosis (ML-IAP).<sup>193</sup> The zinc sites in these domains lie in a trapezoid-like geometry (pdb# 1OYN) with the distances between zinc in domains A and D and B and C being 13.5 Å while all other distances between neighboring zinc sites varies between 26 and 35 Å (Figure 15). Peptides based on the processed N-terminus of Smac/DIABLO can negate the ability of overexpressed ML-IAP or XIAP to suppress drug-induced apoptosis.<sup>193</sup> These peptides have been demonstrated to bind to a single BIR of ML-IAP (protomer E) and the BIR3 of XIAP with similar high affinities ( $\sim 0.5 \mu\text{M}$ ).<sup>193</sup> Protomers A-D form a tetramer with the N-terminus peptide of a neighboring domain binding to the Smac binding site.

A somewhat similar zinc site is seen in one of the ADP ribosylation factors (ARFs), which are members of the Ras superfamily of GTP-binding proteins. Sequences of ARF-GAP domains show no recognizable similarity to those of

**Figure 15** The zinc sites in the five BIR domains of the melanoma inhibitor of apoptosis are arranged in a trapezoid-like geometry (pdb# 1OYN). Structure prepared using DS ViewerPro 5.0 Accelrys Inc. San Diego, CA

other GAPs, and contain a characteristic  $Cx_2Cx_{16-17}Cx_2C$  motif<sup>194</sup> similar to that found for the zinc sites in inhibitor of apoptosis proteins (Table 6). The crystal structure of the ARF-GAP domain comprises a central three-stranded  $\beta$ -sheet flanked by five  $\alpha$ -helices, with a zinc ion coordinated by four cysteines with spacing and secondary structure similar to that found in the zinc sites of the BIR-containing proteins (Table 6).

### 7.3 CH1 Domain

Three zinc ions bound in a triangular relationship are found in the transcriptional coactivators CBP and p300.<sup>195</sup> Adaptation to hypoxia is mediated by transactivation of hypoxia-responsive genes by hypoxia-inducible factor-1 (HIF-1) in complex with the CBP and p300. The domain the zinc ions bind to is referred to as a Cys/His region, CH1. The three zinc ions bind to Cys and His ligands covering 66 amino acids, with no overlaps in the sequence (Table 6). Each binding site contains three Cys and one His ligand. The first two ligands are always a His and Cys with a spacer of 3 and supplied by  $\alpha$ -helices. The spacing varies for the last two Cys ligands. The three zinc sites are at the vertices of a nearly perfect equilateral triangle with 21 to 22 Å distances between zinc ions on the sides of the triangle (pdb# 1P4Q). The zinc ions are critical to the structural stability of this domain since their removal by EDTA yields an NMR spectrum characteristic of an unfolded protein.<sup>195</sup> CH1 serves as a scaffold for folding of the HIF-1 $\alpha$  C-terminal transactivation domain (TAD), which forms a vise-like clamp on the CH1 domain that is stabilized by extensive hydrophobic and polar interactions.

The protein CITED2, which binds p300/CBP, is thought to be a negative regulator of HIF-1 transactivation.<sup>196</sup> The CITED2-TAD binds a more extensive surface of CH1 than does the HIF-1 $\alpha$  C-TAD. However, a conserved amino acid sequence motif, LPxL, in CITED2 and HIF-1 $\alpha$  interacts with an overlapping binding site on CH1 likely accounting for the negative regulation effect.

### 7.4 Zinc Transporters

A number of bacterial metal transporters belong to the family of ATP-binding cassette (ABC) transporter system (see *Metallochaperones & Metal Ion Homeostasis*).<sup>197</sup> These systems constitute one of the most abundant superfamilies of proteins. They are involved in the transport of a wide variety of substances and in many cellular processes. The zinc transporter ZnuA from *E. Coli* and *Synechocystis* sp. 6803, the proposed zinc transporter TroA from *Treponema pallidum*, and the proposed manganese transporter *Streptococcus pneumoniae* surface antigen, PsaA, are placed in cluster 9 of the ABC transporters.<sup>198</sup>

These zinc-binding sites mainly use His ligands and span a relatively great distance in the protein (Table 6).

The periplasmic zinc-binding protein TroA from the human parasite *Treponema pallidum*<sup>199</sup> and pneumococcal surface antigen PsaA<sup>200</sup> are very similar. The bound zinc ion is coordinated by the NE2 nitrogens of His68, His133, His199 and both oxygens of Asp279 in TroA and His67 (NE2), His139 (NE2), and one oxygen of the carboxylates of Glu205 (OE1) and Asp280 (OD1) in PsaA. The latter two His residues of TroA are also further stabilized by H-bonding interactions with the carboxylates of Asp131 and Glu248 (pdb# 1TOA). In the case of PsaA only His139 is observed H-bonding the carboxylate of Asp137 (pdb# 1PsZ). The coordination geometries are described as tetrahedral for PsaA and distorted square pyramidal in TroA owing to the interaction of both oxygens of Asp279. The apex of the pyramid is occupied by the nitrogen of His199 while the other His ligands and the two oxygens of Asp279 make up the square plane.

A similar zinc-binding site is predicted by sequence alignment for Znu.<sup>201</sup> The bound zinc ion is coordinated by the NE2 nitrogens of His83, His179, His243 in a manner quite similar to TroA (Table 6). The latter two His residues are also further stabilized by H-bonding interactions with the carboxylates of Asp177 and Glu261 (pdb# 1PQ4) as in TroA and PsaA. However, the proposed fourth Asp ligand does not bind and is replaced by a water molecule in a large hydrophobic cavity.<sup>201</sup>

The function of the proteins is presumed to be similar to that of members of the periplasmic ligand-binding protein (PLBP) family that function as ligand-binding receptors for active transport and chemotaxis. However, these proteins do not have the flexible interdomain  $\beta$ -strands of the PLBPs. An argument has been proposed for a more rigid hinge (in this case a backbone  $\alpha$ -helix) if the purpose of these proteins is 'small' metal ion transport.<sup>199</sup> Thus, since the free energy difference of zinc in solution and bound to a protein is considered to be small,<sup>202</sup> the binding of zinc to a protein cannot incur the large entropy changes that would be associated with the ordering of a very mobile hinge region.

## 1 INTRODUCTION

### 1.1 Historical Background

Zinc is a relatively recent arrival among the common metals, having been produced commercially in Europe only since the middle of the eighteenth century – in fact in Bristol in 1738. However, its history begins in prehistoric times. The oldest known piece is a Dacian idol discovered in a ruined prehistoric settlement at Dordosch, Transylvania, consisting of zinc of 87% purity. Bracelets in the form of hollow silver rings filled with zinc were made by the early Greeks and were found at Cameiros on the island of Rhodes. In fact, zinc was known in the brasses, alloys of zinc and copper, long before its isolation in a pure state. Brasses were known at least a thousand years before the Christian era; the Romans smelted mixtures of calamine (zinc carbonate) with copper ores to obtain brass.

Knowledge of zinc smelting appears to have come originally from India (13th century) and spread to Sumatra and China, where it was produced commercially by the middle of the eighteenth century: such a sample dated 1745 contained 99% of zinc with tin and iron as impurities. There is evidence that zinc was being imported into Europe from these countries as early as 1611, but zinc smelting in Europe and America really started on a large scale in the nineteenth century in

centers such as Liege, Bristol, and Swansea in Europe and at the Washington arsenal in America.

Zinc compounds were known to the alchemists; several have been in therapeutic use (calamine for skin problems, zinc sulphate for eye treatments) for over a thousand years.

### 1.2 Occurrence and Abundance

Estimates of the abundance of zinc in the sun, in meteorites, in the Earth's core and crust, and in the oceans are very difficult to make,<sup>1</sup> but its abundance in the Earth's crustal rocks and soils is of the order of 100 ppm, about 1000 times as abundant as its congeners cadmium and mercury. All three elements are *Chalcophiles* so that, in the reducing atmosphere that prevailed when the earth's crust solidified, they were deposited in the sulfide phase giving rise to the sulfide ores, their most important source. Later, as weathering took place, zinc became soluble only to be precipitated as the carbonate, silicate, or phosphate.

The main zinc ores are the sulfide ZnS, known as zinc blende in Europe and sphalerite in the United States, and the carbonate ZnCO<sub>3</sub> (calamine in Europe, smithsonite in the United States). Major deposits are found in Canada, Australia, Mexico, Peru, Russia, and the United States. Minor ores include the silicates willemite, Zn<sub>2</sub>SiO<sub>4</sub> and hemimorphite, Zn<sub>4</sub>Si<sub>2</sub>O<sub>7</sub>(OH)<sub>2</sub>·H<sub>2</sub>O. Franklinite, (Zn, Fe)O·Fe<sub>2</sub>O<sub>3</sub>, is mainly a zinc ferrite (see below), but is also important for its manganese content. Zinc also occurs in a number of other minerals, for example, goslarite, ZnSO<sub>4</sub>·7H<sub>2</sub>O, wurtzite, ZnS, zincite, ZnO, and a number of secondary arsenate and phosphate minerals, such as hopeite, Zn<sub>3</sub>(PO<sub>4</sub>)<sub>2</sub>·4H<sub>2</sub>O.<sup>2</sup>

Zinc occurs to the extent of between 5 and 10 × 10<sup>-3</sup> mg L<sup>-1</sup> in seawater, with a residence time of about 2 × 10<sup>4</sup> years; there are significant amounts of zinc in the manganese nodules on the ocean floor. In river waters, there is between 100 mg L<sup>-1</sup> (in the Nile) and 900 mg L<sup>-1</sup> (in the Garonne),<sup>3</sup> mainly in particulate form rather than dissolved. The principal species present in natural waters<sup>4</sup> are Zn<sup>2+</sup>aq, [ZnOH]<sup>+</sup>, ZnCO<sub>3</sub>, and, in the oceans, [ZnCl]<sup>+</sup>. Kinetic processes in natural waters have been reviewed,<sup>5</sup> as have methods for analysing for zinc in natural, potable, and effluent waters.<sup>6</sup>

### 1.3 Biological Importance

Zinc was demonstrated to be an essential trace element for eukaryotes in 1869; it has subsequently been shown to be essential for all life forms.<sup>7-9</sup> It generally plays either a catalytic or a structural role; in some metalloproteins that interact with DNA, zinc appears to play both roles. It is an essential constituent of many enzyme systems, as first demonstrated, for carbonic anhydrase, in 1940. Several hundred zinc metalloenzymes and metalloproteins have now been recognized, in a wide range of organisms. It generally functions at or near the active site, particularly in catalysis of

nucleophilic substitutions. In the early years of bioinorganic chemistry, analytical difficulties and spectroscopic restrictions hampered the investigation of zinc centers in biological systems, but increasingly powerful diffraction, spectroscopic, and other techniques have in recent decades enormously increased understanding of their structure and function. The development during the past decade of fluorescent probes for zinc has also helped in studying the nature and function of zinc-containing species in biological systems. Such probes generally contain an anthracene or fluorescein moiety substituted into a cyclic, acyclic, or tripodal polyamine that can bind firmly to the zinc. Photoinduced electron transfer (PET) sensors operate by the  $\text{Zn}^{2+}$  interrupting the PET of the ligand and restoring or enhancing its fluorescence.<sup>10–12</sup>

The long history and slow early development of the subject has been briefly reviewed (see also *Zinc Enzymes* and *Zinc: DNA-binding Proteins*).<sup>13,14</sup> More recent general reviews of the biological role of zinc, including its regulatory role and the intriguing question of the localization of zinc in particular organs (e.g. parts of the male reproductive system of both plants and animals have high concentrations of zinc, as has the hippocampus in the brain), are available.<sup>15,16</sup> The manifold important zinc-containing biological systems have spawned a multitude of model complexes,<sup>17</sup> thereby greatly enriching knowledge of the coordination chemistry of zinc (see Sections 8 and 9). Types of model complexes include those with amino acid ligands to model zinc-peptide interactions, NNN-donor ligands to model the active site of carbonic anhydrase or carboxypeptidases, NO-donor Schiff bases to model  $\text{Zn}_2$  sites, and  $\mu\text{-O}^{2-}$  and  $\mu\text{-CO}_3^{2-}$  polynuclear complexes to model  $\text{Zn}_3$  and  $\text{Zn}_2\text{Mg}$  active sites. The biological inorganic chemistry, particularly the coordination chemistry of  $\text{Zn}^{2+}$  in biological systems, has been well covered in a number of books<sup>18–20</sup> and several aspects are mentioned elsewhere in this encyclopedia.

### 1.4 Zinc in the Human Body

There is a somewhat more than 2 g of zinc in the average adult; its plasma concentration is about 20  $\mu\text{M}$ . There are believed to be some 200 zinc-requiring enzymes in the human body. Zinc is essential for healthy skin and proper wound healing, for a strong immune system, for bone metabolism, and for normal taste and smell. To maintain the required levels of zinc in the human body, a daily intake of several milligrams is required. Recommended Dietary Allowances (RDA; USA; 1989) are 12 and 15 mg per day for adult females and males respectively; Reference Nutrient Intakes (RNI; UK; 1991) are 9.5 and 7.0 mg per day.<sup>21</sup> Zinc contents of foods are 3 to 4 mg per serving for meat, 1 to 2 mg, for, for example, grains, nuts, cheese (there is very little zinc in fruit), giving a daily intake of the order of 20 mg.<sup>22</sup> But there can be problems of absorption, with the phytates present in many cereals significantly reducing zinc uptake by forming a stable complex that is very poorly absorbed from

the gastrointestinal tract. A low-zinc diet, especially a plant-based diet with high phytate levels, results in slow growth, as first convincingly demonstrated in Iran in the late 1960s. Zinc deficiency reduces testosterone production in men, and delays puberty for male adolescents. Some 30 clinical disorders may be attributed to zinc deficiency; correcting this may be the key to delaying macular degeneration of vision, and to curing anorexia, acne, alcoholism, postnatal depression, and even the common cold.<sup>23</sup> There is a continuing controversy as to whether a large number of people suffer from a modest zinc deficiency in their daily diet; zinc supplements are popular. However, it is important not to exceed daily requirements, as a modest excess of zinc leads to reduced copper absorption and a large excess of zinc is toxic. One gram of zinc sulfate may induce nausea, vomiting, abdominal cramps, and diarrhea; higher doses have proved fatal. Rice polluted with zinc sulfide was implicated in an outbreak of severe skeleto-muscular disorders in Japan. Zinc inhalation can give rise to ‘metal fume fever’, whose symptoms are similar to those of influenza. The nutritional role<sup>24,25</sup> and the toxicity<sup>26,27</sup> of zinc have been considered in detail, its diverse function in the particular context of inorganic microbiology has been explored,<sup>28</sup> and the biological monitoring of zinc has been reviewed.<sup>29</sup>

A number of zinc compounds and complexes have been developed for therapeutic purposes.<sup>30</sup> Several zinc complexes of cyclam-based ligands have proved potent inhibitors of HIV, while hydroxypyridinone complexes are being assessed as insulin mimics for the treatment of diabetes. There is some evidence that the administration of certain zinc chelates may help to ward off strokes, while a suberoylanilide hydroxamate complex has been in clinical trials as an anticancer agent since 2000.

### 1.5 Zinc in Supramolecular Chemistry

A wide range of zinc-based coordination polymers<sup>31</sup> has been developed in recent years, ranging from simple chains to layers, clusters, and a variety of three-dimensional frameworks. Molecular architectures generated include helicates, rotaxanes, catenanes, knots,<sup>32</sup> grids, cylinders, capsules, and various structures containing tailored holes and channels. Such supramolecular assemblies can be valuable in molecular recognition, in catalysis, in separation, and in modeling of biological systems, for example, the ‘biological motors’ that operate flagella and muscles – where zinc is almost certainly involved in association with adenosine phosphates.

Supramolecular entities are prepared either by designed or self-assembly, or by the breakdown of larger species – the so-called ‘bottom-up’ and ‘top-down’ approaches respectively. Most supramolecular zinc compounds have been obtained by self-assembly methods, often operating in a rather hit-and-miss way. However, controlled cleavage of coordination polymers should prove a useful route to predesigned supramolecular assemblies. An example of this approach is provided by the

generation of a supramolecular hexanuclear zinc species from the three-dimensional coordination polymer prepared from zinc acetate and di-2-pyridyl ketone.<sup>33</sup>

## 1.6 General

There are good overviews of zinc chemistry in several inorganic textbooks, especially those by Greenwood and Earnshaw<sup>34</sup> and by Cotton, Wilkinson, and their recent collaborators.<sup>35</sup> Much detailed information, especially on the preparation and properties of binary compounds and salts, can be found in the elderly multivolume treatises of Mellor<sup>36</sup> and Pascal,<sup>37</sup> while Sidgwick's more modest pair of volumes<sup>38</sup> also contains much useful information of this type. The organometallic chemistry of zinc is considered in detail elsewhere (see *Zinc: Organometallic Chemistry*).

## 2 PRODUCTION OF THE ELEMENT

World production of zinc rose from about 300000 tons per annum towards the end of the nineteenth century to about 7 million tons in 1996. Zinc blende is the most important ore of zinc and is usually found in association with galena, PbS, and some mineral detritus from which it is separated by differential flotation. The concentrate is then heated in air to give SO<sub>2</sub>, which is used in sulfuric acid manufacture, and zinc oxide. The latter is then used in either an electrolytic isolation step or in a smelting process. In the former, extensively used in North America and in Tasmania, the oxide is leached out with dilute sulfuric acid and the solution electrolyzed with aluminum cathodes and, usually, lead anodes, the deposited zinc (99.95% pure) being stripped off the cathodes from time to time. Various smelting processes, based on the reduction of ZnO with coke, rely on the low boiling point of zinc (907 °C). Early batchwise procedures using horizontal retorts were superseded by continuous processes using vertical retorts made of silicon carbide. The zinc produced by such procedures was fairly pure but required to be further purified, by fractional distillation or electrolytic refining, to 99.99% for use in die-casting alloys and in high quality brass. The retort processes do not have the thermal efficiency of a blast furnace in which the combustion of the fuel for heating takes place in the same space as the reduction of the oxide. Early attempts at adapting the blast furnace for zinc smelting were unsuccessful, for which there are sound thermodynamic reasons.<sup>39</sup> There are two main difficulties: firstly, ZnO reduction by carbon is not spontaneous below the boiling point of zinc and, secondly, the zinc vapor is a good reducing agent for CO<sub>2</sub> so that, during subsequent cooling of the vapor to condense it, the zinc is liable to be reoxidized to ZnO, with concomitant formation of CO. A solution to the problem is found in the Imperial Smelting Process in which hot Zn and CO from the blast

furnace are passed through a chamber drenched by a spray of molten lead at 550 °C. Zinc dissolves appreciably in lead at this temperature so that it is collected in the lead droplets and passes down with them, too quickly to be oxidized, into a molten lead bath below. The solution of zinc in lead passes to a separate cooler chamber at 440 °C, when the lower solubility of zinc at this temperature causes it to separate from the lead. The molten zinc is run off and the lead returned to the spray chamber. The process can be operated continuously and mixed zinc and lead ores may be used so that both metals can be produced simultaneously.

For small deposits, the ZnS may be converted into ZnCl<sub>2</sub> and thence into the metal. Zinc can also be solubilized from sphalerite by bacterial oxidation.<sup>40</sup>

Technical aspects of the production and of the uses (cf. following section) of the element have been detailed at length.<sup>41</sup>

## 3 USES

The most important of the many uses of zinc is as an anticorrosion agent for iron and steel,<sup>42</sup> in the form of a coating that may be applied by immersion in molten zinc ('hot-dip galvanizing'), electrolytic deposition, spraying with liquid metal, or heating with powdered zinc ('sherardizing' after its inventor Sherard Cowper-Coles). Zinc is also used to prevent corrosion in the form of sacrificial anodes (see *Sacrificial Anode*), particularly in marine applications. Zinc sheeting is used in roof cladding, zinc plates are used in lithography (zinc has a low contact angle with respect to printing inks), and zinc dust is used as a reductant.

A major use is in the manufacture of brasses, alloys of copper and zinc containing about 20–50% zinc, the ductility and tensile strength of which are controlled by the zinc content. The *Phase Rule* diagram of the zinc-copper system is complex: of the six solid solutions that may be formed as the zinc concentration increases over the whole composition range, the practically useful alloys are confined mainly to two, the  $\alpha$  and  $\beta$  (the latter being much harder than the former) and their mixtures. The topic is interesting both from a practical and structural point of view and has been dealt with in detail elsewhere.<sup>43</sup> Small percentages of aluminum, iron, manganese, tin, and nickel are frequently added to 60–40 copper–zinc alloy to increase tensile strength without markedly affecting ductility: these are referred to as 'high tensile brasses' (see *Alloys*).

As a casting metal for pressure die casting into permanent, steel casting dies, zinc is one of the cheapest metals and is widely used to produce small parts of complex shape such as automobile parts (door handles, locks, carburettors, petrol (gasoline) pumps) and is readily chromium plated. The zinc used for such castings must be highly pure to avoid corrosion and disintegration along impurity grain boundaries.

It is alloyed with about 4% Al and 0.02% Mg. The aluminum strengthens the zinc and also prevents the molten alloy from attacking the steel pressure casting dies. Zinc readily reacts with mercury or will displace mercury from a mercury(II) salt to form an amalgam that is useful for reductions, as in the preparation of compounds of the lower oxidation states of transition metals and lanthanides (e.g.  $\text{Cr}^{\text{II}}$ ,  $\text{V}^{\text{II}}$ ,  $\text{Eu}^{\text{II}}$ , dimeric  $\text{Mo}^{\text{III}}$ ) and in analytical chemistry (e.g. in the Jones reductor; see *Analytical Chemistry of the Transition Elements*).

The long-familiar Daniell cell used a zinc electrode; zinc sheeting is still much used in battery manufacture. Useful background material for this aspect of zinc chemistry is to be found in the article *Electrochemistry: Applications in Inorganic Chemistry*, further details elsewhere.<sup>44,45</sup> The original Leclanché battery (1866), based on the cell

was a wet cell. Some two decades later, Geissner patented the idea of manufacturing the zinc anode in the form of a cup that would act as a container for the electrolyte, which was immobilized with plaster of Paris. This development was combined with the use of the manganese dioxide/carbon cathode and an electrolyte immobilized using a cereal paste to form the basis of modern dry cell technology. The discharge mechanism of the Leclanché cell is not as simple as it is sometimes represented. In outline, oxidation of zinc to  $\text{Zn}^{2+}\text{aq}$  occurs at the anode, while at the cathode reduction of  $\text{Mn}^{\text{IV}}$  to  $\text{Mn}^{\text{III}}$ , either as  $\text{MnO}(\text{OH})$  (s) or  $\text{Mn}_2\text{O}_3 \cdot \text{H}_2\text{O}$ , takes place. The initial products of the electrode reactions then undergo further reactions in solution, mainly forming  $[\text{Zn}(\text{NH}_3)_2]^{2+}$ , then slightly soluble  $\text{Zn}(\text{NH}_3)_2\text{Cl}_2$ . For light discharges, an alternative reaction between  $\text{Zn}^{2+}(\text{aq})$  and a  $\text{Mn}^{\text{III}}$  hydroxyoxide can give  $\text{ZnO} \cdot \text{Mn}_2\text{O}_3$ . At lower  $\text{NH}_4^+$  concentrations, chloride and hydroxide or hydroxide alone are preferred ligands to  $\text{NH}_3$ , and a variety of solid complexes are formed, such as  $\text{ZnCl}_2 \cdot 4\text{Zn}(\text{OH})_2$  or simply  $\text{Zn}(\text{OH})_2$ . The main cell reactions can be summarized as

and

However, if the initial ammonium chloride concentration is depleted, the reaction, as indicated above, becomes more complex and formation of hydroxochloro complexes plays an increasingly important role. The zinc alloy sheet used for the anode manufacture contains small quantities of lead and cadmium, and various corrosion inhibitors, such as a soluble mercury salt, are added to improve shelf life.

A variation of the Leclanché cell is the zinc chloride cell in which the ammonium chloride is completely replaced

with zinc chloride. Such cells have a better service capacity at high current drain, at low temperatures, and on continuous discharge.

A further variation of the Leclanché cell is the so-called alkaline manganese cell. The negative pole is a hollow cylinder of powdered amalgamated zinc set in carboxymethylcellulose gel. The current collector is usually made of brass and the interior space is filled with immobilized KOH electrolyte solution. The positive pole consists of a mixture of electrolytic  $\text{MnO}_2$  and graphite in a ratio of 4–5:1 wetted with electrolyte solution. The cell reaction is given approximately by the equation

but in practice is considerably more complicated. The main advantage of alkaline manganese cells over Leclanché cells is their relatively constant capacity over a wide range of current drainage conditions. An interesting feature of these cells is that provided the discharge is limited when the cell voltage reaches about 0.9 V, the cell reaction can be reversed and the system can function as a secondary cell.

The Ruben-Mallory zinc–mercury(II) oxide battery, which revolutionized the battery industry, uses the cell

The anode reaction is

and the cathode reaction may be represented as

The overall cell reaction is then

Important features here are (i) the invariance of the electrolyte solution and (ii) the constancy of the chemical potentials of the reactants and products as the cell is discharged. The former fact means that only a very small quantity of electrolyte is required, giving the cell an almost constant internal resistance and therefore a flat discharge curve; the latter means that, during discharge, the open circuit voltage remains constant, both desirable features in a battery. (The standard free energies of formation of  $\text{Hg(s)}$  and  $\text{Zn(s)}$  are respectively  $-58.4 \text{ kJ mol}^{-1}$  and  $-318.2 \text{ kJ mol}^{-1}$ , giving a free energy change for the cell reaction of  $-259.8 \text{ kJ mol}^{-1}$  and a cell emf of 1.347 V, close to the open circuit voltage of 1.357 V of commercially produced cells.)

The zinc–silver oxide cell, widely used in miniature applications and larger ones in military applications, is closely

related to the zinc–mercury(II) oxide system and has the configuration

The main features of the zinc–silver oxide cell are similar to those of the zinc–mercury(II) oxide system. The principal difference apart from cost is the higher open circuit voltage: the emf calculated from the standard free energies of formation of ZnO and Ag<sub>2</sub>O is 1.593 V, in close agreement with the open circuit voltage of commercial cells of 1.60 V.

Zinc has found application in several other types of battery, including industrially important zinc–air cells in which the oxygen of the air is used as the cathodic reactant in a cell such as

The zinc–air cell has marginally the highest theoretical voltage (1.65 V) of all these zinc-based cells.

All the zinc-based cells, except for the alkaline manganese cell under certain conditions, are primary cells. Secondary (rechargeable) cells are generally based on cadmium rather than zinc, especially in the form of nickel–cadmium cells.

## 4 PROPERTIES OF THE ELEMENT

### 4.1 Physical Properties

Some physical properties of zinc are shown in Table 1. The naturally occurring isotopes, with their abundances, are <sup>64</sup>Zn(48.89%), <sup>66</sup>Zn(27.81%), <sup>67</sup>Zn(4.11%), <sup>68</sup>Zn(18.57%), and <sup>70</sup>Zn(0.62%). Man-made isotopes include <sup>63</sup>Zn ( $\tau_{1/2}$  = 38.1 min;  $E_{\beta^+}$  = 2.32 MeV), <sup>65</sup>Zn ( $\tau_{1/2}$  = 243.6 days;  $E_{\beta^+}$  = 1.353 MeV, EC,  $\gamma$ ), and <sup>69m</sup>Zn ( $\tau_{1/2}$  = 13.9 h;  $E_{IT}$  = 0.4389 MeV,  $\gamma$ ). All three have been used for tracer studies, for example, of zinc absorption; <sup>65</sup>Zn has been used to monitor the performance of diesel engines and to trace the movement of underwater silts and sediments (<sup>65</sup>Zn is incorporated into powdered glass mixed with natural sand); <sup>63</sup>Zn can be used for PET (Positron Emission Tomography); <sup>67</sup>Zn is suitable for Mössbauer and nuclear magnetic resonance (NMR) spectroscopy (see below).

The electron configuration of zinc, [Ar]3d<sup>10</sup>4s<sup>2</sup>, might have been expected to lead to a structure based on close packing of spheres (see Figure 1); such is not the case and the experimental hexagonal close-packed structure is markedly distorted, the axial ratio being nearly 1.9 instead of 1.63 as in perfect hexagonal closest packing. Each Zn atom has six nearest neighbors in its own plane at a distance of 2.659 Å; the other six, three above and three below, in the adjacent planes, are at a greater distance, 2.906 Å. It is not satisfactory simply to regard the atoms in this structure as packing like prolate

**Table 1** Selected physical properties of zinc

|                                                       |                                            |

spheroids, for in the close-packed  $\epsilon$ -phase of the Cu–Zn system the axial ratio is less than 1.63 and one would then have to assume that the atoms are behaving at some compositions as prolate and at others as oblate spheroids. It has been suggested that there is some tendency to form covalent bonds, with dp<sup>2</sup> hybrids playing a part in the basal planes, leading to a smaller interatomic distance in the close-packed planes.

#### 4.1.1 Zinc Mössbauer Spectroscopy

Zinc is one of the few elements with an isotope useful for Mössbauer spectroscopy.<sup>46,47</sup> <sup>67</sup>Zn has a long-lived isomer state, which leads to potentially narrow line widths (as narrow as  $3.2 \times 10^{-4}$  mm s<sup>-1</sup>) in the Mössbauer spectrum. Disadvantages are a smaller cross section than, for example, <sup>57</sup>Fe and a much higher recoil energy, decreasing the rate of recoil-free events. The <sup>67</sup>Zn isomer may be produced using a <sup>67</sup>Ga source.

#### 4.1.2 NMR Spectroscopy in Zinc Systems

The only NMR-active isotope of zinc is <sup>67</sup>Zn, whose resonance is at 6.254 MHz at 2.344 T. Sensitivity with respect to <sup>1</sup>H is only  $2.85 \times 10^{-3}$ , and the natural abundance of <sup>67</sup>Zn is only 4.1%. The nucleus ( $I = 5/2$ ) has a quadrupole moment and because of line broadening this causes difficulties in the study of binding with large ligands, especially in metalloproteins (see **Zinc Enzymes**). Given the low abundance of <sup>67</sup>Zn, Fourier Transform NMR methods are used. For example, in such an NMR study<sup>48</sup> of zinc halide solutions the dependence of the chemical shift on concentration is strongly nonlinear, higher frequencies being observed with increasing concentration, an effect partly ascribed to the change of stereochemistry from octahedral to tetrahedral on passing along the series from [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup> to [ZnX<sub>4</sub>]<sup>2-</sup> (cf. Section 9.2). In contrast, no shifts were observed for perchlorate, nitrate, or sulfate salts, where presumably the zinc-containing species is [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup> throughout.

**Figure 1** The relation of close packing to the structural chemistry of zinc and its compounds. (a) Close-packed identical spheres in a plane surrounding a central sphere (shaded, 1). (b) An equatorial plane through the spheres in (a) showing the location of the centers of holes above and below the equatorial plane. Only three spheres from above the plane may be placed in the positions corresponding to alternate holes, such as those marked T, so as to achieve close packing; the centers of these spheres lie directly over the hole centers. An atom at the center of the T holes is coordinated to the four contact spheres in regular tetrahedral coordination. (c), (d) The two ways of adding three spheres from below the equatorial plane to achieve close packing; in (c) the centers of the upper and lower spheres lie above each other so that the lower ones are located at H in (b). This is hexagonal close packing and is found in the structure of metallic zinc (albeit distorted, see text). In (d) the three lower spheres alternate with respect to the upper ones (i.e. three upper spheres at T, three lower spheres at C, in b). This is cubic close packing and is the foundation of the structures of many zinc compounds (e.g. ZnS, ZnO, see text). (e) Two of the three spheres, 4 and 5, added above the plane form an octahedral hole when sphere 6 is added. Spheres 1–6 surround this hole in an octahedral arrangement that may be represented as shown in (f), (g), or (h). If a zinc atom lies at the center of the octahedral holes and the spheres are, for instance, halogen atoms linked in layers of  $\text{MX}_6$  octahedra sharing edges, this is the so-called cadmium iodide structure adopted by the zinc halides as in (i)

Ligand nuclei have been the subject of many studies; for example,  $^{35}\text{Cl}$  NMR has been used to examine the environment of chelated zinc(II). Molar relaxivity can be used to characterize the zinc environment in terms of the quadrupolar relaxation of  $^{35}\text{Cl}$  that it can produce in 0.5 M NaCl. Bidentate chelation (as with glycinate, glutamate, succinate) increases its effectiveness in producing  $^{35}\text{Cl}$  relaxation. Terdentate chelation (iminodiacetate, aspartate) can either increase or decrease the amount of relaxation caused by zinc; the least relaxation is produced when the ligand atoms have a formal negative charge and a large acidity constant. In some cases, zinc chelated by four ligand atoms (nitrilotriacetate) is effective for  $^{35}\text{Cl}$  relaxation, a good indication that such chelation does not constitute a coordinatively saturated environment. This point is significant in connection with the function of zinc in the active site of zinc metalloenzymes (see *Zinc Enzymes*). Molar relaxivities for 1:1 and 2:1 chelates usually differ and it is possible to derive formation constants that are consistent with literature values determined by other methods. Carbon-13 NMR studies have been widely used to investigate complexing of a variety of organic ligands with zinc. A more exotic example of the use of ligand nuclei to evaluate the properties of zinc-containing species is afforded by the  $^{119}\text{Sn}$  NMR study of a zinc complex derived from a tripodal triamidostannate(II) ligand, viz.  $\text{Zn}[\text{Sn}\{\text{SiMe}_2\text{N}(p\text{-tolyl})\}_3\text{SiMe}_2]_2$ . The NMR results establish the metal-metal bond polarity, X-ray diffraction having shown the Sn-Zn-Sn unit to be linear.<sup>49</sup>

## 4.2 Chemical Properties

Freshly cut zinc is a shiny metal with a bluish lustre but it tarnishes rapidly in moist air, to give a protective coating of  $\text{ZnO}$ ,  $\text{Zn}(\text{OH})_2$ , and  $\text{ZnCO}_3$ . It combines readily with oxygen, sulfur, phosphorus, or the halogens on heating. Nonoxidizing acids dissolve zinc with evolution of hydrogen to give zinc(II) salts that, in aqueous acids, contain the hydrated  $\text{Zn}^{2+}$  ion and often a range of its complexes with the acid anion. With oxidizing acids, the reactions are more complicated: nitric acid, for example, gives a variety of nitrogen oxides (and frequently some of their reduction products) depending on the concentration and temperature. Zinc is the only element of the Zn, Cd, Hg triad to dissolve in aqueous alkali to give ions such as aquated  $[\text{Zn}(\text{OH})_4]^{2-}$ , the zincate ion. Such solutions are technically important in the electrolytic deposition of zinc on aluminum.

Since zinc has a filled d shell, few characteristic transition metal properties are shown and zinc(II) compounds are colorless and diamagnetic. Indeed, zinc shows similarities to magnesium, many of their compounds being isomorphous and, like magnesium, it displays class a (hard) behavior in complexing readily with O-donor ligands (see *Class A & Class B Behavior*). In contrast to magnesium, however, zinc has a much greater tendency to form covalent compounds (e.g.  $\text{ZnO}$  has a tetrahedral wurtzite structure whereas  $\text{MgO}$

has the normal NaCl structure). Zinc does share one feature in common with transition elements and that is its tendency to form a large number of stable complexes not only with O-donor ligands but also with N- and S-donor ligands and with halides, pseudohalides, and cyanide (Section 8). Its versatile complexing behavior places zinc on the class a/b (hard/soft) borderline (see *Class A & Class B Behavior*) and this feature of zinc chemistry is doubtless important in the catalytically active and structural sites of zinc enzymes in which complexation with O-, N-, and S-containing groups from amino acid side chains readily occurs (see also *Zinc Enzymes* and *Zinc: DNA-binding Proteins*). In a more specific resemblance to a transition metal, zinc(II) complexes resemble those of high-spin cobalt(II) in terms of *Kinetic Lability* and *Stereochemistry*; for each element in the +II state it is generally true that four-, five-, and six-coordinated complexes readily interconvert. This is reasonable since, in terms of electron density, high-spin  $3d^5 4s^2$  would be expected to behave similarly to  $3d^{10} 4s^2$ , and the ionic radii are almost identical. Use is made of this in the substitution of cobalt for zinc in zinc metalloenzymes, with minimal structural perturbation, thereby providing a spectroscopically active probe for the active site environment of the metal ion.

## 5 OXIDATION STATE AND STEREOCHEMISTRY

### 5.1 Oxidation State

The Raman spectrum of the glassy solid obtained from a melt of Zn in  $\text{ZnCl}_2$  indicates the presence of the  $(\text{Zn-Zn})^{2+}$  ion, but the chemistry of zinc is dominated by the +II state and, except possibly in the *Pulse Radiolysis* of complexes of  $\text{Zn}^{2+}$ , for example, those of cyclic ligands (L) such  $[\text{14}] \text{ane-1,4,8,11-N}_4$  where species of the type  $\text{LZn}^+$  have been detected, and the radical ligand complex of the same stoichiometry where L = the radical anion of glyoxal bis(*N-t*-butylamine) generated in the cavity of an electron spin resonance (ESR) spectrometer, the role of zinc(I), real or apparent, is minimal so far as the general chemistry of zinc is concerned. It is interesting, however, that the  $\text{Zn}^+$  ion is formed, albeit slowly ( $k < 10^5 \text{ M}^{-1} \text{ s}^{-1}$ ), by the reaction of the *Hydrated Electron* with  $\text{Zn}^{2+}$ . The  $\text{Zn}^+$  species is a powerful reductant and from the *Marcus Treatment* of the reduction of  $[\text{Ru}(\text{NH}_3)_6]^{3+}$  it is estimated that  $E^\circ(\text{Zn}^{2+}/+)$  is approximately  $-1.0 \text{ V}$ ; other estimates are even more negative.

### 5.2 Coordination Numbers and Stereochemistry

The key one-volume source of information on inorganic structures remains the overview by Wells,<sup>50</sup> the source of most unattributed structural information in this article. It is necessary to trace specific zinc compounds through

**Table 2** Stereochemistry of Some Zinc(II) Compounds

| Coordination number | Stereochemistry                                      | Example                                                                                                                                                                   |

Wells's formula index as well as consulting his general discussion of zinc compounds. Coordination numbers of Zn<sup>2+</sup> in its compounds and complexes range from 2 to 8 (Table 2). The filled d shell confers no crystal field stabilization on Zn<sup>2+</sup> (see *Crystal Field Stabilization Energy*) and coordination number and stereochemistry are determined by the size of the Zn<sup>2+</sup> cation and the *Steric requirements* of the ligands. Both tetrahedral and octahedral geometry are commonly found in complexes, though essentially all Zn<sup>2+</sup> ions in biological systems are in tetrahedral coordination. Several zinc complexes are mentioned in a recent review of seven-coordinate complexes.<sup>51</sup> Where ligands bind by chelation (see *Chelating Ligands*), and quite often even where ligands are monodentate, distortions from regular geometries are widespread.

Six-coordinate complexes may be octahedral or trigonal prismatic. The synthesis of a number of six- and five-coordinate complexes with amino acids and pyrazole throws light on the factors involved both in the determination of the geometry of six coordination and on possible mechanisms of interconversion through a five-coordinate intermediate or transition state.<sup>52</sup> Zn<sup>2+</sup> can exhibit two coordination numbers in the same compound – indeed the unit cell of the maltol complex [Zn(malt)<sub>2</sub>]·1.5H<sub>2</sub>O contains both five- and six-coordinate Zn<sup>2+</sup> ions.<sup>53</sup> Both five- and six-coordinate cations have been found in a binuclear complex of an unsymmetrical compartmental ligand,<sup>54</sup> in a tetrazinc metallacrown species,<sup>55</sup> and in the bis-Zn<sup>2+</sup> complex of a ligand containing both a bipy and a terpy unit. Zn<sup>2+</sup> occupies both octahedral and trigonal bipyramidal sites in Zn<sub>3</sub>V<sub>4</sub>(PO<sub>4</sub>)<sub>6</sub>, and square pyramidal sites in Zn<sub>2</sub>(VO)(PO<sub>4</sub>)<sub>2</sub>,<sup>56</sup> while Zn is found in trigonal planar, tetrahedral, and trigonal bipyramidal sites in [Zn<sub>4</sub>(thf)<sub>4</sub>(MeZn)<sub>4</sub>(O<sub>3</sub>SiR)<sub>4</sub>], where R = –N(SiMe<sub>3</sub>)(2,6-*i*-Pr<sub>2</sub>C<sub>6</sub>H<sub>3</sub>).<sup>57</sup> Such metallasiloxanes can act as models for zinc-containing zeolite catalysts, which have recently been reported to facilitate a range of organic reactions.

## 6 BINARY COMPOUNDS

### 6.1 Zinc Hydride, Carbide, and Related Compounds

Zinc hydride, a moderately stable solid slowly decomposed by water, may be prepared by the reaction of LiH, NaH, or LiAlH<sub>4</sub> on a zinc halide such as the bromide or iodide. If organometallic derivatives of zinc of the type Li<sub>*n*</sub>ZnR<sub>*n*+2</sub> are treated with LiAlH<sub>4</sub>, complex hydrides such as LiZnH<sub>3</sub>, Li<sub>2</sub>ZnH<sub>4</sub>, and Li<sub>3</sub>ZnH<sub>5</sub> may be prepared.

The carbide ZnC<sub>2</sub> may be regarded as an acetylide containing the C<sub>2</sub><sup>2-</sup> ion. A zinc carbene, ZnCH<sub>2</sub>, can be prepared by the *Matrix Isolation* technique; it undergoes a carbene-carbyne change to HZnCH on UV irradiation. The carbene may possibly be regarded as a radical ion pair formed by transfer of an electron from Zn to CH<sub>2</sub> to give an anionic carbene.<sup>58,59</sup>

Zinc alkyls and aryls are reactive to air and water and their reactions are similar to, but less vigorous than, those of Grignard reagents, from which they differ in the important respect that they do not react with CO<sub>2</sub> and are usually prepared in an atmosphere of this gas. Zinc may be used to generate, in effect, the nucleophile <sup>–</sup>CH<sub>2</sub>CO<sub>2</sub>R from α-halo esters that can then react with carbonyl compounds as in the well-known Reformatsky reaction:

Metal–hydrogen and metal–carbon bond strengths, including some values for zinc, have been reviewed.<sup>60</sup>

### 6.2 Compounds with Group 15 Elements

Zinc nitride, Zn<sub>3</sub>N<sub>2</sub>, may be prepared by heating zinc amide, Zn(NH<sub>2</sub>)<sub>2</sub>, to 330 °C or by heating zinc dust to 600 °C in a stream of ammonia. It is regarded as an ionic nitride containing the N<sup>3-</sup> ions in an α-Mn<sub>2</sub>O<sub>3</sub> structure in which the zinc ions have four tetrahedral neighbors and N has two types of distorted octahedral coordination groups. The radius of the nitride ion in this and similar nitrides is close to 1.5 Å, larger than that of most metal ions.

Zinc phosphides, which include Zn<sub>3</sub>P<sub>2</sub>, Zn<sub>7</sub>P<sub>10</sub>, ZnP<sub>2</sub> (α- and β-forms), and ZnP<sub>4</sub>, may be prepared from the elements. The structure of Zn<sub>3</sub>P<sub>2</sub> is closely related to that of Zn<sub>3</sub>N<sub>2</sub>: the zinc atoms are surrounded tetrahedrally by four P but each P is surrounded by six Zn at six of the vertices of a distorted cube. The compound is used as a lubrication additive and as a pesticide and rodenticide. It works as a poison by releasing phosphine in the rat's stomach. Phosphidozincates M[ZnP]<sub>2</sub> are known for M = Ca, Sr, Ba, Cd; the Sr<sup>2+</sup> salt has been shown to have the calcium aluminum silicide structure, consisting of layers of edge-shared ZnP<sub>4</sub> tetrahedra alternating with Sr<sup>2+</sup> layers.<sup>61</sup>

Zinc antimonides (Zn<sub>3</sub>Sb<sub>2</sub>, Zn<sub>4</sub>Sb<sub>3</sub>, and ZnSb) are semiconductors.

### 6.3 Compounds with Group 16 Elements

Tetrahedral coordination is again a dominant theme. All the monochalcogenides adopt either a wurtzite or zinc blende structure, described below, in which the metal is tetrahedrally coordinated. Various aspects of close packing in relation to the structures of ZnO, ZnS, and other zinc compounds are depicted in Figure 1.

#### 6.3.1 Zinc Oxide, Zinc Hydroxide, and Zincates

ZnO is the most important manufactured zinc compound; it was known long before the metal itself. The technical product is made by burning in air the zinc vapor obtained on smelting the ore but this can contain a few tenths of a per cent of lead as an impurity. A purer product is made from the vapor of refined zinc. It is a finely divided white solid with the wurtzite structure (cf. Figure 1 and zinc sulfide below). On heating, it changes to a yellow colored solid: this is associated with the evaporation of oxygen from the lattice to give a nonstoichiometric phase  $\text{ZnO}_{1-x}$  ( $x \leq 70$  ppm).<sup>62</sup> The excess zinc atoms produce lattice defects that can be excited by absorption of visible light, and by ‘doping’ zinc oxide with an excess of 0.02–0.03% zinc metal a range of colors – yellow, green, brown, or red – can be obtained. The photophysics of zinc oxide and its functioning as an archetypal binary compound semiconductor have been reviewed,<sup>63</sup> and the self-assembly of zinc oxide into nanorods reported.<sup>64</sup>

The major use of zinc oxide is in rubber production, where it lowers the vulcanization temperature and shortens vulcanization time. It is also used as a pigment in paints, ‘zinc white’ in oils and ‘chinese white’ in water colors, having the twin advantages compared with ‘white lead’ (the ‘flake white’ or Cremnitz white of the artist), a basic lead carbonate, that it is nontoxic. Also, since zinc sulfide is white, it is not discolored by sulfur compounds. It has the disadvantages compared with  $\text{TiO}_2$  (see *Titanium: Inorganic & Coordination Chemistry*) of a lower refractive index and therefore a lower covering power, sometimes used to advantage by the artist. In some paint vehicles, it is inclined to give a brittle paint film and consequent durability problems. However, it improves the chemical durability of glass and for this reason is used in the production of special glasses, both opaque and transparent, and in enamels and glazes. It is used as the starting material for a range of other zinc chemicals such as zinc soaps (zinc salts of the longer chain fatty acids) that are used as paint driers, fungicides, and stabilizers in plastics. It is used in the production of zinc silicate,  $\text{Zn}_2\text{SiO}_4$ , for television screen manufacture. A minor but important use is in the manufacture of ‘zinc ferrites’ (see *Ferrite*). These are *Spinel*s,  $\text{Zn}_x\text{M}_{1-x}^{\text{II}}\text{Fe}_2^{\text{III}}\text{O}_4$ , having the second metal, M, in oxidation state two (M is frequently Mn or Ni). When  $x = 0$  the structure is that of an inverse spinel (i.e. half the  $\text{Fe}^{\text{III}}$  ions occupy tetrahedral sites in the close-packed array of oxide ions, the other half of the  $\text{Fe}^{\text{III}}$  ions occupying octahedral

sites), and when  $x = 1$  it is that of a normal spinel in which all the  $\text{Fe}^{\text{III}}$  ions occupy octahedral sites because  $\text{Zn}^{\text{II}}$  displaces  $\text{Fe}^{\text{III}}$  at the tetrahedral sites. Lowering the fraction of  $\text{Fe}^{\text{III}}$  ions in the tetrahedral sites lowers the *Curie Temperature*. The magnetic properties of the ferrite are therefore controllable by adjustment of the zinc content. Thin films of zinc oxide have excellent piezoelectric properties and high transmittance and are used in transducers, gas sensors, surface acoustic wave devices, solar cell windows, and transparent conducting films;<sup>65</sup> spectra of transparent colloidal suspensions of very small zinc oxide particles have been reported.<sup>66</sup> Zinc oxide is also used for desulphurization of, inter alios, carbon dioxide, and feedstocks for catalytic processes, and in  $\text{ZnO}/\text{Cr}_2\text{O}_3$  catalysts for high-pressure synthesis of methanol.<sup>67</sup> There are also a number of medicinal and cosmetic uses for zinc oxide – it is used in various dermatological treatments, alone or mixed with  $\text{Bi}_2\text{O}_3$  or bismuth subgallate in the treatment of hemorrhoids, in dental cements, in sun screens, and to give ‘body’ to cosmetic formulations.

ZnO is amphoteric, dissolving in acids to form salts containing the hydrated zinc(II) cation (cf. Section 9.1), which may be more or less complexed with the acid anion depending upon its affinity for zinc and on concentration. Zinc oxide dissolves in alkalis to form zincates such as  $[\text{Zn}(\text{OH})_3]^-$  and  $[\text{Zn}(\text{OH})_4]^{2-}$ . Various salts of these hydroxy-ions have been structurally characterized. Zinc also forms zincates of the type  $\text{M}^{\text{II}}\text{ZnO}_2$ , where  $\text{M} = \text{Sr}$  or  $\text{Ba}$ , and  $\text{M}^{\text{I}}\text{M}'^{\text{I}}\text{ZnO}$ , where  $\text{M}^{\text{I}}, \text{M}'^{\text{I}} = \text{Li}, \text{Na}, \text{K}$  variously. These are prepared from the respective component oxides. In  $\text{SrZnO}_2$ , layers of  $\text{ZnO}_4$  tetrahedra, sharing all vertices, provide sites for  $\text{Sr}^{2+}$  ions in seven coordination between the layers, whereas in  $\text{BaZnO}_2$  the  $\text{ZnO}_4$  tetrahedra form a quartz-like framework containing  $\text{Ba}^{2+}$  ions in positions of irregular eight coordination.

An important structure in the chemistry of hydroxy (and carbonate) derivatives of zinc is the so-called  $\text{CdI}_2$  (or brucite,  $\text{Mg}(\text{OH})_2$ ) structure. This structure may be represented in various ways – Figure 1(a) shows one representation. From this close-packed description, it follows that because different layer sequences are possible there is a very large number of closely related structures (more than 80 such structures have been characterized). Zinc hydroxide, for example, exists in a number of forms based on this structure but with differing layer sequences; one of them has the simple  $\text{CdI}_2$  structure, others have more complex layer sequences and one, the  $\gamma$ -form, has an entirely different structure consisting of rings of three tetrahedral  $\text{Zn}(\text{OH})_4$  units that are linked through their remaining vertices into infinite columns (Figure 2). The upper vertices ( $x$ ) of the tetrahedra of one ring are the lower vertices ( $y$ ) of the ring above, thus sharing all the vertices within the column and giving the composition  $\text{Zn}(\text{OH})_2$ . Each column is linked to neighboring ones by hydrogen bonds.

A number of zinc hydroxy compounds are based on the  $\text{CdI}_2$  layer structure but with zinc ions attached to the outside of the layer. Since the I atoms are close packed in a  $\text{CdI}_2$  layer, there are two kinds of site on either side of such a layer for

**Figure 2** The coordination of zinc in  $\gamma$ -Zn(OH)<sub>2</sub>

additional metal ions: above an occupied octahedral interstice or above an empty tetrahedral site. On electrostatic grounds, neither type of site is suitable for a straightforward addition of the metal ion to the layer because of the proximity to either one or three cations of the layer. This difficulty is overcome in the first case by removing the metal ion from within the layer (Figure 3). The mineral chalcophanite,  $\text{ZnMn}_3\text{O}_7 \cdot 3\text{H}_2\text{O}$ , has layers of the simplest cadmium iodide type (cf. Figure 1) derived from  $\text{Mn}^{4+}$  and  $\text{O}^{2-}$  ions from which one-seventh of the metal ions have been removed, giving the composition  $\text{Mn}_3\text{O}_7$  instead of  $\text{MnO}_2$ . Bound to each side of this layer directly above and below the unoccupied  $\text{Mn}^{4+}$  positions are  $\text{Zn}^{2+}$  ions and between the uncharged layers are layers of water molecules, three of which complete the octahedral coordination of the  $\text{Zn}^{2+}$ .

In the hydroxy chloride  $\text{Zn}_5(\text{OH})_8\text{Cl}_2 \cdot \text{H}_2\text{O}$ , the structure is based on charged layers with chloride ions and water molecules in between. One-quarter of the zinc ions are missing from a  $\text{Zn}(\text{OH})_2$  layer, and for each absent  $\text{Zn}^{2+}$  two such ions are added beyond the surfaces of the layer so that the composition is  $\text{Zn}_5(\text{OH})_8^{2+}$ . The charge is balanced by the chloride ions between the layers. The  $\text{Zn}^{2+}$  ions are tetrahedrally coordinated on the outer surfaces of the

layers, in contrast to octahedrally coordinated  $\text{Zn}^{2+}$  within the layers. A similar structure is found in the hydroxy nitrate,  $\text{Zn}_5(\text{OH})_8(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$ . Closely related to these structures is one in which the layers are linked by bonds to the  $\text{Zn}^{2+}$  ions on the surface: the compound in question is hydrozincite,  $\text{Zn}_5(\text{OH})_6(\text{CO}_3)_2$ , formed during the corrosion of zinc and in the weathering of zinc ores. Again one-quarter of the  $\text{Zn}^{2+}$  are absent from a  $\text{Zn}(\text{OH})_2$  layer and replaced by twice their number of zincs, equally distributed on either side of the layer. In addition, there is replacement of one-quarter of the  $\text{OH}^-$  ions in the layer by O atoms of  $\text{CO}_3^{2-}$  ions, giving the composition  $\text{Zn}_2[\text{Zn}_3(\text{OH})_6](\text{CO}_3)_2$  instead of  $\text{Zn}_4(\text{OH})_8$  of the parent compound. A second O atom of each  $\text{CO}_3^{2-}$  is bonded to the surface Zn atoms, which are tetrahedrally coordinated as in the hydroxy chloride (see Figure 3). Since there is bonding between the Zn and O throughout the structure in its entirety, this is not a layer structure although its relation to one is clear. The close-packed layers of O atoms around octahedrally coordinated Zn atoms are again a prominent feature of the structure. All these structures illustrate the ease with which zinc is able to enter into tetrahedral and octahedral coordination.

In addition to the normal oxide,  $\text{ZnO}$ , a peroxide  $\text{MO}_2$  is also known. This decomposes slowly at ambient temperature, but nonetheless has been used as an astringent, a deodorant, and a vulcanizing agent.

### 6.3.2 Zinc Sulfide

$\text{ZnS}$ , zinc blende or sphalerite, is the most common ore of zinc, but it is also found in a rarer mineral, wurtzite, which is the more stable at high temperatures. These minerals are important archetypal structures found in many other AB compounds that are essentially nonionic and these structures bear the names of the respective minerals. In both, each Zn is tetrahedrally coordinated by four S and each S is coordinated tetrahedrally by four Zn. The structures differ only in the type

**Figure 3** Removal of a metal ion from a close-packed  $\text{CdI}_2$ -type layer to the surface: diagrammatic representation of its occurrence in the structures of some zinc compounds

of close packing: it is cubic in zinc blende and hexagonal in wurtzite (see Figure 1).

When pure, ZnS is white and is used as a pigment that, when coprecipitated with barium sulphate, gives the white pigment 'lithopone'. Various grades are produced containing 26–60% ZnS; it is more opaque than zinc white and when suspended in water or oil has thixotropic properties. Its commercial importance has greatly decreased, however, since the introduction of titanium pigments. Zinc sulfide when freshly precipitated dissolves easily in mineral acids with evolution of  $\text{H}_2\text{S}$ , but roasting renders it far less reactive and it is then used as a harmless nontoxic pigment.

Zinc sulfide turns gray on exposure to UV light, probably due to some dissociation into the elements, a process that is inhibited by trace addition of cobalt salts. X-rays, radioactivity, and cathode rays produce fluorescence or luminescence in a variety of colors (e.g. traces of copper give a greenish phosphorescence after exposure to light or in the presence of a trace of a radioactive compound). The range of colors can be extended by changing the trace metal added or by the replacement of zinc by Cd and of S by Se. It is widely used in the manufacture of cathode-ray tubes and of luminous dials. Zinc sulfide is a semiconductor; Mn-doped zinc sulfide nanoparticles have promising optical properties.<sup>68</sup>

### 6.3.3 Zinc Selenide and Telluride

Zinc selenide (yellow) and telluride (brown) have similar structures to those of the sulfide, both existing in both wurtzite and zinc blende modifications. The selenide is used with zinc sulfide as a phosphor. It has the interesting property that it can act as a blue–green solid state laser: blue–green laser action in solids is rare (most solid-state lasers function towards the red end, 635 nm or more, of the spectrum). At room temperature, laser action with the selenide at a wavelength of 525 nm (green) is observed and at  $-196^\circ\text{C}$  at 495 nm (blue). Unfortunately the laser is relatively short-lived. Zinc telluride is a wide band gap semiconductor whose electron transport properties in the form of thin films of stoichiometric and nonstoichiometric forms have been much studied.<sup>69,70</sup> Its applications in optoelectronics, for example, as an optical recording material, have been reviewed.<sup>71</sup>

## 6.4 Zinc Halides and Pseudohalides

All four halides are known. In the gas phase, they consist of linear  $\text{X-Zn-X}$  molecules with internuclear distances (in Å) as a function of X as follows: F, 1.81; Cl, 2.05; Br, 2.21; I, 2.38. The difluoride has the highest melting point ( $872^\circ\text{C}$ ), the melting points rising thereafter from chloride to bromide to iodide (275, 394, and  $446^\circ\text{C}$ , respectively).  $\text{ZnF}_2$  may be prepared by the action of HF on the metal or by the action of heat on the tetrafluoroborate  $\text{Zn}(\text{BF}_4)_2$ . It has the typically ionic 6:3 rutile structure in which zinc is six coordinated by

$\text{F}^-$  ions. This stereochemistry persists in the complex fluoride  $\text{KZnF}_3$ , which has the ideal perovskite structure. Although its solubility is low,  $\text{ZnF}_2$  may be crystallized as a tetrahydrate from aqueous solutions. The nearly anhydrous compound has been used in the fluorination of organic compounds and has been used in the manufacture of phosphors for fluorescent lights, glazes, and enamels for porcelain, for preserving wood, and in electroplating.

$\text{ZnCl}_2$ ,  $\text{ZnBr}_2$ , and  $\text{ZnI}_2$  are hygroscopic with extremely high solubilities in water, which is able to dissolve about four times its mass of  $\text{ZnX}_2$ . Aqueous methods of preparation give hydrates, of which a number are known. The halides are best prepared anhydrous by the usual dry methods such as treating the heated metals with HCl,  $\text{Br}_2$ , or  $\text{I}_2$ , as required. Water-free solutions of  $\text{ZnX}_2$  may also be prepared by treating a suspension of finely divided zinc in an inert solvent with the appropriate halogen.

The chloride, bromide, and iodide show properties characteristic of covalent compounds such as solubility in ethanol, acetone, methyl cyanide, and other organic solvents. They also have comparatively low-melting points, and crystal structures based on a two-dimensional array that may be regarded as derived from a close-packed lattice of halide ions in which the zinc ions occupy the tetrahedral sites. The crystal chemistry of  $\text{ZnCl}_2$  is more complex than at first appeared. Three polymorphs were originally described that, although they can be regarded as having approximately close-packed chloride ions, had different layer sequences. It has been found, however, that the structure is extremely sensitive to the presence of water and if crystallization is carried out with rigorous exclusion of water, an orthorhombic hexagonal close-packed structure is formed that changes into one of the other structures on exposure to the atmosphere. The presence of  $\text{OH}^-$  ions formed on exposure to moisture may facilitate the rearrangement of the layers. The hcp structure is the only stable one for  $\text{ZnCl}_2$ . All four structures consist of tetrahedral  $\text{ZnCl}_4$  groups, each sharing vertices with four others. The bromide is also based on tetrahedral  $\text{MX}_4$  units. The iodide has a unique structure: one-quarter of the tetrahedral interstices in a ccp array of I atoms are occupied in groups of four to form supertetrahedral  $\text{Zn}_4\text{I}_{10}$  groups, which are joined by sharing four vertices to form a three-dimensional structure. The structures of all three halides contrast strikingly with those of the typically ionic  $\text{MX}_2$  halides. Molten  $\text{ZnCl}_2$  has a remarkably high viscosity at its melting point and an X-ray diffraction study indicates that the liquid consists of  $\text{Zn}^{2+}$  and  $[\text{ZnCl}_4]^{2-}$  ions, rather than molecular  $\text{ZnCl}_2$ . On the other hand, the temperature dependence of the viscosity and the electrical conductance of the liquid has been interpreted in terms of polymeric species  $[\text{ZnCl}_2]_x$  and free  $\text{Zn}^{2+}$  and  $\text{Cl}^-$  ions arising from dissociation of the salt.

Zinc chloride has a large number of uses. It has been used as a deodorant, disinfecting, and embalming material; alone or with phenols or other fungicides in the preservation of railway sleepers (ties); for fireproofing timber; with ammonium

chloride as a flux for soldering (it readily dissolves other oxides); for etching metals; in the manufacture of parchment paper, artificial silk, dyes, activated carbon, cold-water glues, and vulcanized fiber; for browning steel, galvanizing iron, copper plating iron; in magnesia cements, and with zinc oxide in dental cements; in petroleum oil refining; in cements for metals and for facing stone; as a mordant in printing and dyeing textiles; for carbonizing woollen goods; in producing crepe and crimping fabrics; for mercerizing cotton, sizing and weighting fabrics, and vulcanizing rubber; as a solvent for cellulose; for preserving anatomical specimens; in microscopy for separating silk, wool, and plant fibers; as a dehydrating agent and catalyst in some organic syntheses. Its astringent properties make it useful in dentistry as a dentine desensitizer and in veterinary practice in the treatment of ulcers and similar conditions.

Zinc bromide is used in making silver bromide collodion emulsions for photography and in the shielding of viewing windows for nuclear reactions.

Zinc cyanide has a three-dimensional structure with tetrahedral zinc and coordination to both C and N of the cyanide, the latter lying along the line joining the zincs in the tetrahedral array of zincs in its anticuprite structure.  $\text{Zn}[\text{C}(\text{CN})_3]_2$  has a rutile-related infinite framework in which trigonal carbon centers are linked via  $-\text{C}\equiv\text{N}-$  units to half as many octahedral zinc(II) centers; the structure resembles knitting and exhibits a twofold penetration.<sup>72</sup> Zinc thiocyanate in the solid consists of thiocyanate-bridged tetrahedral  $\text{ZnN}_4$  and  $\text{ZnS}_4$  centers; it decomposes on heating to give  $\text{ZnS}$ .

## 7 SALTS

### 7.1 Oxoanion Salts: Preparation, Properties, and Structures

The salts are prepared by the usual neutralization methods. They are generally isomorphous with the corresponding salts of magnesium but are not thermally as stable. The nitrate, sulfate, and carbonate all decompose ultimately to the oxide on heating. Many of the salts, such as the nitrate, perchlorate, and sulfate, are very soluble in water and often form more than one hydrate; octahedral  $\text{Zn}(\text{H}_2\text{O})_6^{2+}$  units are usually present when there is sufficient water of crystallization. Attempts to prepare anhydrous salts by heating give hydroxy salts. The volatile anhydrous nitrate may be prepared by the action of  $\text{N}_2\text{O}_4$  in ethyl acetate or methyl cyanide on the metal. The zinc phosphates provide a range of structures— $\alpha\text{-Zn}_3(\text{PO}_4)_2$  contains ribbons of  $\text{ZnO}_4$  tetrahedra,  $\beta\text{-Zn}_3(\text{PO}_4)_2$  contains  $\text{ZnO}_4$  and  $\text{ZnO}_5$  polyhedra, while  $\text{Zn}(\text{HPO}_4)\cdot\text{H}_2\text{O}$  consists of H-bonded sheets of linked  $\text{ZnO}_3$  and  $\text{ZnO}_6$  polyhedra. Templated hydrothermal syntheses in the presence of organic bases, for example, triethylenetetramine or piperazine (whose protonated forms provide the necessary cations),

gives a variety of zincophosphate (and zincoarsenate<sup>73</sup>) anions,<sup>74</sup> all of which contain zinc in  $\text{ZnO}_4$  tetrahedra. Such compounds generally have infinite structures, such as 3D frameworks ( $[\text{Zn}_2\text{P}_2\text{O}_8]^{2-}$  and  $[\text{Zn}_3(\text{PO}_4)_2(\text{HPO}_4)]^{2-}$  consist of  $\text{ZnO}_4$  and  $\text{PO}_4$  tetrahedra, the latter ion with 1D channels), 2D layers (e.g.  $[\text{Zn}_2(\text{HPO}_4)_3]^{2-}$  and  $[\text{Zn}_4\text{P}_4\text{O}_{16}]^{2-}$ ), and 1D ladders (e.g.  $[\text{Zn}(\text{HPO}_4)_2]^{2-}$ ).<sup>75</sup> The use of creatinine as template permitted the synthesis of the first uncharged cluster,  $\text{C}_4\text{H}_7\text{N}_3\text{O}\cdot\text{Zn}(\text{H}_2\text{O})(\text{HPO}_4)$ .<sup>76</sup> It is fairly easy to transform low dimensional structures, such as 1D ladders, into 2D and 3D structures. Zinc phosphonates appear in intercalated layer, pillared, and porous forms;<sup>77</sup> the complex prepared hydrothermally from *N*-methyliminobis(methylenephosphonic acid) is monoclinic, comprising a 3D network of phosphonate-bridged  $\text{ZnO}_4$  tetrahedra.<sup>78</sup> Zinc 2-aminoethylphosphate has a phosphate-bridged infinite chain structure; it provides a useful model for metal–phosphate interactions.<sup>79</sup>

Anhydrous zinc acetate may be prepared from zinc nitrate and acetic anhydride; the dihydrate may be crystallized from dilute acetic acid. The zinc in the dihydrate is in an octahedral environment with *trans* diaxial water ligands and bidentate chelating (see *Chelating Ligands*) acetate groups. In the anhydrous salt, the zinc is in a distorted tetrahedral environment with bridging acetate groups. Distillation of zinc acetate gives a crystalline basic acetate  $[\text{Zn}_4\text{O}(\text{OCOMe})_6]$ , the structure of which (1) is analogous to that of basic beryllium acetate. The two compounds are isomorphous; in each the metal is coordinated by four oxygens, three from bridging acetate groups and the fourth lying at the center of the tetrahedron of zinc ions. The two compounds differ in that the zinc complex is hydrolyzed rapidly in water. Absorption and emission spectra of  $[\text{Zn}_4\text{O}(\text{OCOMe})_6]$  have been investigated<sup>80</sup> as well as the X-ray PES (Photoelectron Spectroscopy), and a theoretical treatment shows how well this complex throws light on the electronic structure of zinc oxide itself.<sup>81</sup> The complex is photoluminescent and has a *Ligand-to-Metal Charge Transfer* band, a feature not shown by simple  $[\text{ZnX}_4]^{2-}$  complexes. Other basic carboxylates  $[\text{Zn}_4\text{O}(\text{RCO}_2)_6]$  with R = for example, Et, or *n*-Pr, or  $\text{NEt}_2$  are known.

The crystal structures of a wide range of carboxylates have been described, the main features being that octahedral and tetrahedral coordination, sometimes distorted, are commonly observed and polymeric structures, especially with polyfunctional ligands, are frequently found.

## 7.2 Oxoanion Salts: Uses

Zinc sulfate has been used in rayon manufacture, as a mordant in calico printing, for preserving wood and skins, for clarifying glue, in electrodeposition processes, and in the manufacture of other zinc salts. Thus, for example, zinc nitrite cannot be prepared from aqueous solutions because of rapid hydrolysis but it can be prepared by treating sodium nitrite with zinc sulfate in alcohol. Zinc sulfate also has medicinal uses, in eye lotions and drops, in postoperative tissue healing, and as an emetic. It is also used as a zinc supplement, as also are zinc gluconate, zinc citrate, and zinc picolinate. Zinc phosphate is used in dental cements and temporary fillings. Zinc carbonate and basic zinc carbonate have, alongside zinc oxide, been used since the time of Ancient Egypt to treat a variety of skin conditions (Calamine Lotion, and a variety of ointments and dusting powders).

Several zinc salts act as, or can be doped to give, pigments.<sup>82</sup> Zinc germanate doped with  $V^{4+}$  (cf. zircon purple,  $V^{4+}$  doped into  $ZrGeO_4$ ) and  $Fe^{3+}$  doped into  $ZnGa_2O_4$  give brown pigments; the brown color of the latter can be varied by varying the  $Fe^{3+}$  content. Zinc chromate(VI) is a useful yellow pigment widely used in metal priming paints. Zinc in a silicate matrix is used as a gray pigment in primers; a zincosilicate has been synthesized that acts as a molecular sieve containing three-membered rings.<sup>83</sup>

Zinc acetate is used in wood preservation, as a mordant in dyeing, and in the manufacture of glazes for painting on porcelain. Zinc citrate is used in toothpastes and mouthwashes – it inhibits plaque growth.<sup>84</sup> The sulfanilate and several carboxylates, for example, propionate, caprylate, and undecenoate, find use in skin dusting powders and as fungicides. Zinc *p*-phenolsulfonate has been used in insecticide formulations and in veterinary practice for the treatment of ulcers. Polymerization of metal-containing monomers in the matrix of a different polymer or compound can lead to dramatic modification of properties; for example, of the tensile strength of materials such as polyethylene, where zinc acrylates and acrylamide complexes are useful in this context in giving rise to cross-linking that is controllable by adjusting the concentration of the zinc compound.

## 7.3 Other Salts

Zinc thiocyanate forms colorless deliquescent crystals, but zinc cyanide is insoluble in water. The salts  $Zn_3[Co(CN)_6]_2$  and  $Zn_3[Fe(CN)_5(NO)]_2$  can act as molecular sieves. The former can separate hexane isomers, thanks to the large holes arising from anion vacancies.<sup>85</sup> The latter has no large holes, but can separate methane from carbon dioxide.  $Zn[Au(CN)_2]_2$  has a quartz-like structure with  $-NCAuCN-$  units bridging tetrahedral zinc centers.<sup>86</sup> Zinc cyanamide,  $ZnCN_2$ , a nonpolluting white pigment, has a structure in which  $ZnN_4$  tetrahedra form  $Zn_4N_4$  rings that in turn form twisted chains.<sup>87</sup> Zinc also forms a number of stable fluoroanion

salts, such as  $Zn(BF_4)_2$  (see Section 6.4) and water-soluble  $ZnSiF_6 \cdot H_2O$ .

## 8 COORDINATION CHEMISTRY

Zinc has an extensive coordination chemistry, though less extensive than that of some of the preceding 3d elements. Tetrahedral complexes are particularly readily formed with halides and with a variety of O-donors. Numerous stable complexes are formed with N-donors such as  $NH_3$ , amines, and azaheterocycles, but complexing to phosphines is limited. Complexes with S-donors are common; several have unusual structural features. Zinc complexes have in recent years assumed considerable importance in the generation and self-assembly of a great range of 1-, 2-, and 3-D infinite structures and frameworks, of which a few examples are cited below.  $Zn^{2+}$  has also recently proved useful as a templating cation for the preparation of a variety of macrocycles, rotaxanes, catenanes, and molecular knots, though it must be admitted that its importance in this area, though increasing, is much less than that of  $Cu^+$ .<sup>88</sup>

Zinc(II) complexes of amino acid, peptide, nucleotide, and nucleoside ligands are of obvious biological significance. We mention them here as they illustrate well the variety of coordination modes exhibited by tetrahedral  $Zn^{2+}$ . Individual amino acids can bind through one or more N, O, or S-donor atoms. In metalloenzymes (see **Zinc Enzymes** and **Zinc: DNA-binding Proteins**) and metalloenzyme models, the overall coordination environment of the  $Zn^{2+}$  is usually NNN, NNO, or NNS, with water in the fourth position. The most common ligating residues are histidine, glutamate, aspartate, and cysteine – the  $Zn^{2+}$  is, for example, bonded to cysteine and histidine in zinc finger proteins. The area is well covered in the introductory chapters of several standard bioinorganic chemistry textbooks; the amino acid moieties bonded to the zinc in 21 zinc enzymes have been detailed.<sup>89</sup> Many zinc metalloproteins contain  $Zn^{2+}$  bound to one or more imidazole ligands of the amino acid residue histidine (**2a**). Purely in terms of mode of coordination of the ligand, it is interesting to note that, where more than one histidine coordinates to the metal ion, coordination is not always through the same N atom of the imidazole ring. Thus, in carbonic anhydrase, in which the zinc is bound to three histidines and a water molecule, two of the histidines, which are on the same strand of  $\beta$ -pleated sheet separated by one amino acid residue, bind through the N(3') atom of the imidazole ring whereas the imidazole of the third histidine, lying in an adjacent strand of  $\beta$ -pleated sheet, binds through the N(1') atom (**2b**). A distorted tetrahedral coordination results that has some unusual features: one of the N(3')-zinc distances is the same as the N(1')-zinc distances. Furthermore, the two N(3') atoms are not bound equivalently: one of them is 0.4 Å further from the zinc atom than the other one and the imidazole bearing it is also the most exposed. The

latter may well be concerned with the hydration mechanism of the enzyme<sup>90,91</sup> (see also *Zinc Enzymes*). The role of the coordination chemistry of  $\text{Zn}^{2+}$  in the mechanisms of action of carbonic anhydrase, carboxypeptidase, and alcohol dehydrogenase has been reviewed.<sup>92</sup>

Very thorough and comprehensively referenced surveys of the coordination chemistry of zinc are available. In each of these multivolume compendia, there is an article devoted to zinc complexes,<sup>93</sup> but there are also numerous mentions of zinc complexes in the introductory volumes and in the volumes on applications and uses.<sup>94</sup> Thermodynamic data ( $\Delta H_f^\circ$ ,  $\Delta S_f^\circ$ ,  $\Delta G_f^\circ$ ; also some  $\Delta X^\circ$  values for e.g.  $\text{ZnX}_2 + 2\text{L}$ ) are available for about 100 zinc complexes.<sup>95</sup> In this present encyclopedia, we are only able to mention a very small selection of the more important and interesting complexes. Preparations, structures, properties, and uses are dealt with in this section, the solution chemistry of zinc complexes in later sections (Sections 9.2 and 9.3).

### 8.1 N-Donors

In salts of  $[\text{Zn}(\text{NCS})_4]^{2-}$ , the thiocyanate ligand is N-bonded, whereas it is S-bonded to cadmium in  $[\text{Cd}(\text{SCN})_4]^{2-}$  salts, reflecting the respective hard and soft characters of the respective metal ions. Zinc complexes with the azide ion are well known; crystallographic determinations of the structures of the compounds  $\text{M}_2\text{Zn}(\text{N}_3)_4$  ( $\text{M} = \text{K}$  or  $\text{Cs}$ ) show the presence of discrete  $[\text{Zn}(\text{N}_3)_4]^{2-}$  tetrahedra with linear azide groups. Some of the complexes in this category, such as those with hydrazine and azide, for example  $[\text{Zn}(\text{N}_2\text{H}_4)_2(\text{N}_3)_2]$ , are of interest as primary explosives and care is needed in their manipulation. The 2,2'-dipyridylamine-azide complexes  $[\text{Zn}(\text{dpa})(\text{N}_3)_2]$  and  $[\text{Zn}(\text{dpa})(\text{N}_3)(\text{NO}_3)]$ , which have infinite 2D and 3D structures respectively, display fluorescence and phosphorescence.<sup>96</sup>

The complexes  $[\text{M}(\text{NH}_3)_4]^{2+}$  and  $[\text{M}(\text{NH}_3)_6]^{2+}$  ( $\text{M} = \text{Zn}$  or  $\text{Cd}$ ) have long been known. They have tetrahedral and octahedral coordination, respectively. Interestingly, the Zn–N distance in the tetrammine complex is shorter than that in the analogous  $\text{N}_4$  bis-1,2-ethanediamine chelate,  $[\text{Zn}(\text{en})_2]^{2+}$ . Raman and IR studies, including  $^{15}\text{N}$  labelling, have been used in the calculation of the force constants for the M–N bond in these complexes. The force constant increases with decreasing coordination number and also decreases from zinc to cadmium. Zinc ammine complexes can function as host lattices. For example, the compounds  $[\text{M}(\text{NH}_3)_2\text{Ni}(\text{CN})_4]$ , where  $\text{M} = \text{Zn}$  (or  $\text{Cd}$ ), which consist of two-dimensional polymeric sheets of tetracyanonickelate ions bridged by coordinating diamminezinc(II) cations, function as host lattices for the clathration (see *Clathrate*) of small aromatic molecules such as thiophen, furan, pyrrole, or pyridine; IR studies indicate hydrogen-bonding between the host lattice ammonia ligands and the aromatic guest molecules.

Less work has been done on the complexes of amines,  $\text{RNH}_2$ , than on those with polyfunctional amines such as 1,2-diaminoethane, and to a lesser extent its *N*-alkylated derivatives, for which a large body of data exists. Tetrahedral and octahedral coordination again feature prominently in the structures of these compounds, though with some interesting variations. For example, the hydrido complex  $[\text{ZnH}(\text{MeNCH}_2\text{CH}_2\text{NMe}_2)]$  (3) is dimeric; each zinc atom has a terminal hydride bonded to it and is also bonded to three nitrogen atoms to give a distorted tetrahedral  $\text{N}_3\text{H}$  environment.

In relation to polyfunctional amines, it is interesting to observe the way in which the chelating properties of a ligand (see *Chelating Ligands*) vary with the metal: in studies on the chelating behavior of the triamine  $\text{H}_2\text{N}(\text{CH}_2)_2\text{NH}(\text{CH}_2)_4\text{NH}_2$  (L) towards copper, nickel, and zinc, the five complexes  $\text{ML}^{2+}$ ,  $\text{ML}_2^{2+}$ ,  $\text{MHL}^{3+}$ ,  $\text{M}(\text{HL})_2^{4+}$ , and  $\text{MHL}_2^{3+}$  are common to all three metals. In addition,  $\text{Cu}^{2+}$  and  $\text{Zn}^{2+}$  form the hydroxo complexes  $[\text{Cu}(\text{OH})\text{L}]^+$ ,  $[\text{Zn}(\text{OH})\text{L}]^+$ , and  $[\text{Zn}(\text{OH})_2\text{L}]$ . With regard to the complex  $\text{ML}^{2+}$ , the amine acts as a *Bidentate Ligand* towards  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  and in a terdentate manner towards  $\text{Cu}^{2+}$ , the latter containing both five- and seven-membered rings. On the other hand, the  $\text{ML}_2^{2+}$  complexes contain only five-membered rings, with both amine ligands acting in a bidentate manner.

The catalytic properties of polyazamacrocyclic complexes of the transition metals and zinc<sup>97</sup> represent an active

area of investigation that began on a large scale in the 1960s. Macrocyclic ligands that can bind two different metal ions (Zn,Co; Zn,Mn) in six- and four-coordination sites within the same ligand are interesting both from the catalytic and the structural point of view.<sup>98</sup> The cation of  $[\text{Zn}_3(\text{triscyclam})](\text{NO}_3)_6$  is trinuclear, with a  $\text{Zn}^{2+}$  in each of the macrocyclic rings of the triscyclam ligand, which consists of three cyclam units linked by a pair of  $-\text{CH}_2-p\text{-C}_6\text{H}_4-\text{CH}_2-$  bridges.<sup>99</sup>

Complexes of pyridine, substituted pyridines, and ligands containing fused pyridine rings (bipyridyls and 1,10-phenanthrolines) have been widely studied. Many of these complexes have interesting photophysical properties (*see Photochemistry of Transition Metal Complexes*). The suberate ( $^-\text{O}_2\text{C}(\text{CH}_2)_6\text{CO}_2^-$ ) hydrate of  $[\text{Zn}(\text{phen})_3]^{2+}$  has a three-dimensional hydrogen-bonded network with the cations in tunnels in the structure; suberate, glutarate, and succinate can all bridge pairs of  $[\text{Zn}(\text{phen})_2]$  units to give binuclear complexes.<sup>100</sup> Early studies of bipyridyl complexes concentrated on the 2,2'-isomer,<sup>101</sup> but in recent years there has been increasing interest in the 4,4'-isomer, arising from the numerous structural possibilities inherent in its bridging properties. The compound  $\text{Zn}(4,4'\text{-bipy})\text{SiF}_6 \cdot 2\text{H}_2\text{O}$  has a structure consisting of interpenetrating perpendicular square grid sheets, each sheet stretching to infinity. Each zinc is octahedrally coordinated to four pyridine nitrogens with two water molecules in *trans* positions; the four pyridine rings about each zinc are arranged in propeller fashion and the 4,4'-ligand bridges the zinc centers.<sup>102</sup> 4,4'-Bipyridyl, and analogs containing units such as  $-\text{C}\equiv\text{C}-$  linking the pyridine rings, can be used to build a range of coordination frameworks consisting of penetrating and noninterpenetrating ladders.<sup>103</sup> In fact, ligands containing the 2,2'-diimine chelating group of 2,2'-bipyridyl can also be used to generate clusters and supramolecular species, though to achieve this it is necessary to have two such units in the potential linking ligand, as, for example, in Schiff bases of the type  $\text{RN}=\text{CHCH}=\text{N}(p\text{-C}_6\text{H}_4)_2\text{N}=\text{CH}-\text{CH}=\text{NR}$ . Three-coordinate zinc complexes of the extremely sterically demanding diazabutadiene ligand  $\text{RN}=\text{CMe}-\text{CMe}=\text{NR}$  with  $\text{R} = 2,6\text{-}^i\text{Pr}_2\text{C}_6\text{H}_3$  (the third ligand is alkyl or  $\text{N}(\text{SiMe}_3)_2$ ) are catalysts for ring-opening polymerization of propene oxide and  $\epsilon$ -caprolactone, thanks to the relatively high Lewis acidity of the zinc and its accessibility in this low-coordination number environment.<sup>104</sup> Both  $\text{Zn}^{2+}$  ions are five coordinate in a dimeric rotaxane containing phen and terpy units in each monomeric component. Addition of an excess of  $\text{Cu}^+$  to this doubly threaded molecular assembly displaces the zinc, and decreases the length of the molecule from 83 to 65 Å as the threads slide along each other so that the  $\text{Cu}^+$  ions are both coordinated by two phen moieties.<sup>105</sup>

Pyrazine, piperazine, and pyrazole<sup>106</sup> are, like 4,4'-bipyridyl, suitable ligands for bridging pairs of  $\text{Zn}^{2+}$  ions to give a variety of polynuclear species, while multifunctional (bi)pyridine-pyrazine ligands give scope for the assembly

of various supramolecular assemblies. Using pyrazine with two 2,2'-bipyridinyl substituents as bridging ligands leads to chiral molecular squares, which can be considered to be circular helicates,<sup>107</sup> while diffusion of a methanolic solution of zinc iodide into a nitrobenzene/methanol solution of 2,4,6-tris(4-pyridyl)triazine, tptz, gives a complex with a doubly interpenetrated 3D network structure. This latter species crystallizes with guest nitrobenzene molecules, whose reversible release from the complex gives rise to contraction and expansion without disturbing the overall structure – behavior described as 'springlike' by its discoverers.<sup>108</sup>

Pyrazole rings are also important as constituents of the tripodal ligands colloquially known as scorpionates (polypyrazolylborates and polypyrazolylmethane), which family includes ligands with NNN-, NNO-, and NNS-donor sets.<sup>109,110</sup> Zinc complexes of hydrotris(pyrazolyl)borate ligands have been used to elucidate drug-metalloprotein interactions<sup>111</sup> and to model carbonic anhydrase and several hydrolysis enzymes.<sup>112</sup> Imidazole can also act as a component of similar tripodal ligands. Thus, reaction of zinc acetate with the ligand consisting of three imidazol-1-ylmethyl groups attached at the 2,4,6-positions benzene gives a complex whose structure is described as one-dimensional tubelike.<sup>113</sup>

Porphyrin and phthalocyanine complexes show many interesting features, including their photochemical and photophysical properties. Zinc phthalocyanine complexes have good photosensitizing properties for photodynamic therapy, PDT. In a polymetallic system containing a zinc porphyrin and silver, a photoinduced charge separation occurs giving rise to a long-lived ( $\tau = 1.4$  ms) charge-separated state of the complex.<sup>114</sup> The limit of charge separation is redox reaction, which in the case of zinc complexes generally involves redox at the ligand. Both porphyrins and phthalocyanines can act as  $\pi$ -electron acceptors or donors, to give radical ligands bonded to  $\text{Zn}^{2+}$ .<sup>115</sup> Much effort has been devoted to varying the electronic properties of ligand substituents to tune redox potentials.<sup>116</sup> There is currently considerable interest in assembly and self-assembly of zinc porphyrins,<sup>117</sup> for example the generation of a nonameric porphyrin array.<sup>118</sup> A phosphine-substituted porphyrin zinc complex has been found to be a useful building block for supramolecular assemblies thanks to the high affinity of phosphines for ruthenium(II) centers.<sup>119</sup> Several groups have demonstrated that porphyrin dimers have a high affinity for [60]fullerene; a high affinity for [60]fullerene has now been found for a dendritic hexa-zinc-porphyrin receptor.<sup>120</sup>

## 8.2 O-Donors

Water is a good O-donor ligand, both in the solid state, where many crystal hydrates, for example, of the sulphate, bromate, and perchlorate, contain octahedral  $[\text{Zn}(\text{H}_2\text{O}_6)]^{2+}$ , with  $\text{Zn}-\text{O}$  2.08–2.14 Å, and in solution ( $\text{Zn}^{2+}\text{aq}$  is discussed in Section 9.1 below).

**Figure 4** Bond distances in the coordination of nitrate ligands in the  $[\text{Zn}(\text{NO}_3)_4]^{2-}$  ion

$[\text{Zn}(\text{NO}_3)_4]^{2-}$ , which can be isolated as its tetraphenylarsonium salt, has a distorted dodecahedral structure,<sup>121</sup> each nitrate functioning as a bidentate chelating ligand (see *Bidentate Ligand* and *Chelating Ligands*) through two oxygen atoms to give eight-coordinated zinc. The nitrate coordination is not symmetrical (Figure 4), the longer bond to zinc corresponding to the shorter N–O bond and vice versa, the asymmetry tending towards tetrahedral coordination for the zinc.

Monodentate perchlorate complexes of zinc have been identified.<sup>122</sup> The  $\text{NO}_2^-$  ion can, like  $\text{NO}_3^-$ , function either as a monodentate or as a chelating ligand<sup>123</sup> depending upon the steric requirements of other ligands present in the complex. Interestingly, nitrobenzene can also function as a mono-O- or bidentate O,O'-donor, which it does in ternary complexes also containing the  $-\text{OTeF}_5^-$  ligand.<sup>124</sup> Carbonate can act as a monodentate or bidentate ligand – in the binuclear complex  $[(\text{bipy})_2(\text{H}_2\text{O})\text{Zn}(\mu\text{-CO}_3)\text{Zn}(\text{bipy})_2]^{2+}$ , isolated as its nitrate heptahydrate, the bridging carbonate acts in both capacities.<sup>125</sup> Indeed, tetrahedral, trigonal bipyramidal, and octahedral sites have been identified in various carbonate-bridged polynuclear zinc complexes;<sup>126</sup> carbonate is able to act in a  $\mu_1$ ,  $\mu_2$ ,  $\mu_3$ , or even  $\mu_4$  fashion in this type of complex. Zinc complexes of benzoates and related carboxylates have long been studied as catalysts for the coupling of epoxides with carbon dioxide to afford polycarbonates. Dissolution of the 2,6-difluoro- or 2,6-dichloro-benzoates – the former complex is heptanuclear with  $\mu$ -benzoate and  $\mu_4$ -oxo ligands – in pyridine gives mononuclear ternary complexes.<sup>127</sup> Dicarboxylates as bridging ligands for  $[\text{Zn}(\text{phen})_2]$  moieties are mentioned in Section 8.1.

Phosphate and vanadate complexes of zinc show a diversity of coordination behavior.  $\text{Zn}^{2+}$  accelerates polyphosphate hydrolysis (Section 9.3); appropriate zinc-organic phosphate complexes provide models for ATP transport and biological phosphate transfer, and are of possible relevance to DNA and RNA polymerases (see *Zinc: DNA-binding Proteins*).

As with oxoanion salts, a number of interesting structures are found with simple organic species as ligands, for example, a crystal-structure determination of the tetrameric methylzinc(II) methoxide,  $\{\text{MeZn}(\text{OMe})\}_4$ , reveals the structure (4) in which zinc and oxygen are each tetrahedrally coordinated. Closely related to this structure is that of the polymerization catalyst  $\text{Zn}(\text{OMe})_2(\text{EtZnOMe})_6$  (5). The complex is centrosymmetric and consists of two

enantiomorphic cubes sharing a corner at which a zinc atom is situated; the zincs occupy the corners of a tetrahedron and the oxygens the corners of an interpenetrating, but smaller, tetrahedron. The structure illustrates the occurrence of both four- and six-coordinated zinc in the same structure. It is interesting that mass spectroscopic investigations of the complexes  $\text{MeZnOR}$  ( $\text{R} = \text{Me}$ ,  $\text{Et}$ , or  $t\text{-Bu}$ ) show that all form oligomers in the gaseous state having either six or seven monomer units. So far as solution reactions are concerned, depending on the molar ratio of reactants, the reaction of  $\text{NaOMe}$  with  $\text{ZnCl}_2$  in  $\text{MeOH}$  produces the complex ions:  $[\text{Zn}(\text{OMe})_4]^{2-}$ ,  $[\text{Zn}(\text{OMe})_3(\text{MeOH})]^-$ ,  $[\text{ZnCl}(\text{OMe})_2]^-$ , and  $[\text{Zn}_2\text{Cl}_4(\text{OMe})]^{2-}$ . The last complex is postulated to have methoxide bridges rather than bridging chlorides; analogous reactions occur with sodium isopropoxide. The synthesis, properties, structures, and uses (e.g. as precursors for ceramics) of alkoxides have been reviewed.<sup>128</sup>

Complexes of  $\text{Zn}^{2+}$  with carbohydrates such as D-fructose and D-galactose have been isolated. Complexes with ethers, simple or crown, are rare, though it is possible to prepare zinc salts of several crown ethers from ethylene oxide and zinc fluoroanions in the presence of  $\text{BF}_3$ . An interesting template synthesis of ether-containing ligands with metal-ether bonds has been described in which zinc (and cadmium) are used to template the condensation; this contrasts with their usual inactivity in analogous aza systems.<sup>129</sup> Complexes with aldehydes and simple carbonyl compounds coordinated through oxygen in  $\eta^1$  mode are also rare but bonding of an aromatic aldehyde, as well as acetone, in this way to zinc

in the compounds  $[\text{Zn}(\text{EC}_6\text{H}_4\text{-}t\text{-Bu}_3)_2(p\text{-O=CHOCHOMe})]_2$  ( $\text{E} = \text{S}, \text{Se}$ ) has been reported.<sup>130</sup> On the other hand,  $\beta$ -diketones have long been studied as ligands for zinc. With acetylacetonone, zinc achieves both five and six coordination in the trimer  $[\text{Zn}(\text{acac})_2]_3$  (**6**). The complex  $[\text{Zn}(\text{acac})_2(\text{H}_2\text{O})]$  has a distorted bipyramidal structure. Complexes of the  $\beta$ -diketone itself, as opposed to those of the  $\beta$ -diketonate anion, are rare but such complexes have been described in the cases of  $[\text{Zn}(\text{acacH})_3][\text{InCl}_4]$  and  $[\text{Zn}(\text{MeCOCH}_2\text{CO}_2\text{Et})_3][\text{InCl}_4]$ . Five coordination at zinc is also found in  $[\text{ZnL}_2][\text{ClO}_4]_2$  [ $\text{L} = o$ -phenylenebis(dimethylarsine oxide)], which consists of dimeric cations,  $[\text{ZnL}_2]_2^{4+}$ , with approximately trigonal bipyramidal coordination about each zinc.

Zinc complexes with hydroxypyranones, for example, maltol or kojic acid, have been known for many years.<sup>131,132</sup> These, and analogous complexes with hydroxypyridinones, have been assessed as zinc supplements in cases of severe zinc deficiency, and more recently as potential insulin mimics.

### 8.3 N/O Donors

There are several series of important complexes in which zinc is coordinated by O,N-donor ligands, in particular, amino acid and aminocarboxylate anions. Both types of ligand frequently chelate metal ions through  $>\text{NCH}_2\text{CH}_2\text{CO}_2^-$  units. The aminocarboxylate group contains not only such familiar ligands as ethylenediaminetetraacetate (EDTA) and nitrilotriacetate (nta), but also a number of polyazamacrocyclic ligands bearing pendant methylene carboxylate groups. Complexes of such high-denticity ligands are stabilized by both the chelate effect and the macrocyclic effect (*see Macrocyclic Ligands*), and can be extremely inert to substitution, that is, dissociate extremely slowly.  $\text{Zn}^{2+}$  forms complexes with a variety of cryptands, for example,  $\text{N}[(\text{CH}_2)_n\text{NHCH}_2\text{-}o\text{-C}_6\text{H}_4\text{O}(\text{CH}_2)_2]_3\text{N}$ , with  $n = 1, 2$ , or  $3$ . Anthracene derivatives of these ligands can act as fluorescent  $\text{Zn}^{2+}$  sensors (cf. Section 1.3 above).<sup>133</sup> Cryptands incorporating longer chains, for example  $\text{N}[(\text{CH}_2)_2\text{NH}(\text{CH}_2)_2\text{O}(\text{CH}_2)_2\text{NH}(\text{CH}_2)_2]_3\text{N}$ , can form stable binuclear complexes, in which the two  $\text{Zn}^{2+}$  ions are 4 to 5 Å apart. There is little metal-metal interaction at such separations, indeed it is possible to bridge the two metal centers by adding an appropriate small anion or molecule. A chiral hexaazatriphenolic macrocycle has been synthesized in

efforts to model the active site of P1 nuclease. This macrocycle forms  $\text{Zn}_3$  and  $\text{Zn}_2\text{Cu}$  trinuclear complexes. The  $\text{Zn}^{2+}$  ions in the  $\text{Zn}_3$  complex have  $\text{N}_2\text{O}_2$  and  $\text{N}_2\text{O}_3$  coordination shells; the two  $\text{N}_2\text{O}_3$  coordinated ions are bridged by acetate in the active site model.<sup>134</sup> Zinc complexes of calixarene-imidazole ligands mimic the active sites of other zinc enzymes.

NO-Donor Schiff bases (*see Schiff Base*), particularly multidentate ones, are powerful ligands and many examples of their zinc complexes are known. Zinc(II) often promotes formation of such Schiff bases, for example, those from salicylaldehyde and 1,2-diaminoethane or 1,3-diaminopropane.<sup>135</sup> An interesting feature here is that these ligands readily exert a stereochemical control over the complex and thereby provide many examples of unusual geometry about the central ion, illustrating once more the coordination flexibility of zinc. An example is provided by the complex (**7**),  $[\text{ZnLCl}_2]\cdot\text{H}_2\text{O}$  ( $\text{L} = 2, 6$ -diacetylpyridine dioxime), in which the metal is in a distorted trigonal bipyramidal environment. Schiff bases incorporating aliphatic or phenolic hydroxy groups as well as tertiary or pyridine nitrogens can give binuclear ( $\text{Zn}_2$  or e.g.  $\text{ZnCu}$ ) complexes. Such Schiff bases may be linear, tri- or tetrapodal,<sup>136</sup> or macrocyclic.<sup>137</sup>

Zinc will dissolve in a solution of oxine (8-hydroxyquinoline). The anhydrous complex  $\text{Zn}(\text{oxinate})_2$  is a linear tetramer with bridging oxygens; the two central zinc atoms are six-coordinated octahedral and the two terminal zincs are five-coordinated trigonal bipyramidal units ( $\text{Zn-O}$  between 1.97 and 2.18 Å). This structure is reminiscent of that of the  $\text{Zn}(\text{acac})_2$  trimer.<sup>138</sup> Zinc complexes of oxines with a  $p\text{-NC}_6\text{H}_4\text{NMe}_2$  group linked to the 5-position are luminescent, and potentially of interest in relation to OLEDs (Organic Light Emitting Devices).<sup>139</sup>

In hydroxylamine complexes of the type  $\text{ZnX}_2\text{L}_2$  ( $\text{X} = \text{Cl}, \text{Br}$ , or  $0.5\text{SO}_4$ ), coordination to zinc can be through either N or O depending on the method of preparation (with Cd, coordination is exclusively to N). In the corresponding *O*-methyl derivative,  $\text{ZnCl}_2(\text{MeONH}_2)_2$ , bonding is through nitrogen. A substantial number of hydrazide complexes using  $\text{RCONHNH}_2$  as a ligand are known and the ligand usually binds through the carbonyl oxygen and the  $\text{NH}_2$  nitrogen atom when R is unbranched, but through N only when R is branched, for example, when  $\text{R} = i\text{Pr}$ . Much of the interest in amides as ligands has been directed towards the factors that control the alternative O- or N-binding modes adopted in these compounds. With simple

amides, L, such as acetamide or *N,N*-dimethylacetamide, in complexes of the type  $L_2ZnX_2$  ( $X$  = halide or SCN), the coordination is tetrahedral to oxygen. On the other hand, binding of  $Zn^{II}$  enhances amide deprotonation of *N,N*-bis(2'-pyridinecarboxamide)-1,2-benzene (**8**),  $LH_2$ , to give planar  $[ZnL \cdot H_2O]$ , having maximum electron delocalization; here coordination of the amide oxygens is hindered by the resulting decrease in the chelating ability of the ligand.

An interesting case in which the stereochemistry of zinc coordination is controlled by the local environment is provided by the heteronuclear chelate complex (**9**) in which planar  $Ni^{II}$  selects the  $N_2O_2$  sites and the  $Zn^{II}$  the  $O_2O_2$  sites. Coordinated pyridine completes five coordination for the zinc. The  $Zn-O$  distances average 1.95 Å to the terminal oxygens and 2.09 Å to the bridging oxygens. The zinc is displaced from the basal plane by 0.32 Å towards the pyridine.<sup>140</sup>

#### 8.4 S, S/N, and S/O Donors

Complexes of dithiolene anions, such as maleonitriledithiolate and toluene dithiolate, where the delocalized  $S-C-C-S$  unit chelates the metal ion (see *Chelating Ligands*), are interesting from several points of view.<sup>141</sup> These include the frequent occurrence of square-planar and trigonal prismatic coordination geometries, the often extensive charge transfer, which can lead to unusual formal oxidation states (spectra of  $[Zn^{II}(mnt)_2]^{2-}$  in dichloromethane, suggest a  $Zn^{III}$  complex containing an  $mnt^{3-}$  radical ligand), and their potentially valuable conductivity, optical, and magnetic properties. The recently reported first molecular magnetic semiconductors are based on 1,3-dithiol-2-thione-4,5-dithiolate ligands.  $Zn^{2+}$ -dithiolene centers occur in several essential enzymes.

Sulfur- and selenium-donor ligands stabilize several polynuclear zinc complexes, for example, the  $[E_4Zn_4(SPh)_{16}]^{4-}$  ( $E = S$  or  $Se$ ) anions, prepared as their  $Me_4N^+$  salts.<sup>142</sup> The complex  $[Zn_4(SPh)_{10}]^{2-}$  forms a ground-state charge transfer complex with methyl viologen.<sup>143</sup> These

zinc-sulfur anions, and also  $[Zn_4(SPh)_4]^{2-}$ , all contain tetrahedral  $ZnS_4$  units. They may be regarded as fragments of the cubic  $ZnS$  lattice. The benzylthiolate complex  $[Zn_4(SBz)_{10}]^{2-}$  has an adamantane framework;  $[Zn_8(S)(SBz)_{16}]^{2-}$  incorporates a cuboctahedral framework.<sup>144</sup> Self-assembly of a zinc-cyclen complex with thiocyanuric acid gives a  $Zn_{12}$  supramolecular capsule consisting of a cuboctahedral framework enclosing a tetrahedral cavity in which lipophilic organic molecules of appropriate size, for example, adamantane or 2,4-dinitrophenol, can be accommodated as guests.<sup>145</sup>  $[Zn_8(SPh)_{16}Cl]^-$  consists of a tetracapped tetrahedron of zincs with the  $Cl^-$  at the center; 12 thiolate ligands act as bridging edge groups, four are terminal. The thiophosphate  $Zn_3(PS_4)_2$  contains  $ZnS_4$  and  $PS_4$  tetrahedra; the former form corner-shared two-dimensional layers.<sup>146</sup> Reaction of zinc perchlorate with bis(2-aminoethanethiolato)zinc in aqueous acetonitrile gives polynuclear complexes with  $Zn_3S_3$  and  $Zn_4S_4$  cores; all zincs also bear N-donor ligands.<sup>147</sup> Zinc diethyldithiocarbamate is a rubber preservative; zinc halide thiosemicarbazone complexes show promising second-order nonlinear optical properties.

Complexes with the thio-oxamate ligands  $NH_2(CO)CSO^-$  and  $NH_2(CS)CO_2^-$ , which bind through O and S, exhibit trigonal bipyramidal geometry around the zinc.<sup>148</sup> The zinc complex of the O,S-donor ligand 2-pyridinethiolate 1-oxide, known as zinc pyrithione, is a fungicide and bactericide much used in hair shampoos.

Thiolate-thioether complexes with  $S_2S'_2N$  donor sets provide useful models for such bioinorganic systems as alcohol dehydrogenase and zinc fingers<sup>149</sup> (cf. start of this Section). The affinity of  $Zn^{2+}$  for nitrogen/sulfur donor ligands means that there are a few zinc complexes of thioazacryptands, as well as complexes of standard (aza)cryptands. Nitrogen- and sulfur-containing macrocyclic ligands are important in the modeling of enzymes and transmembrane metal ion carriers.<sup>150</sup>

#### 8.5 Halide, Cyanide, and Thiocyanate Complexes

Complex anions  $[ZnX_4]^{2-}$  are readily obtained for  $X = Cl$ ,  $Br$ , or  $I$ , though not for  $X = F$ . They may be isolated as solids using the standard technique of precipitation using a large cation such as  $[Ph_4As]^+$  or  $[Co(NH_3)_6]^{3+}$ . Zinc chloride readily accepts chloride ions to form tetrahedral  $[ZnCl_4]^{2-}$  complexes, and a large number of structural studies on these and related complexes have been carried out. For example, the crystal structure of  $Cs_2ZnCl_4$  contains this ion with very little distortion from tetrahedral,<sup>151</sup> but it is interesting that in the complex  $[Co(NH_3)_6][ZnCl_4][Cl]$  the same anion shows marked distortion ( $Zn-Cl = 2.22$  to  $2.36$  Å;  $\angle Cl-Zn-Cl = 101.6$  to  $115.4^\circ$ ). Calculations indicate that the major cause of the bond length distortion is anisotropy in the applied electrostatic crystal forces.<sup>152</sup> Other cases of deviation from tetrahedral geometry caused by packing forces are known, for example, the  $[ZnI_4]^{2-}$  ion in its salt with the 2,4-dimethyl-1*H*-1,5-benzodiazepinium cation has

strict  $C_2$  symmetry. These findings suggest that care should be exercised in other cases when seeking explanations for stereochemical distortions in a complex in the solid state in terms of electronic and bonding effects within the complex itself. The  $[\text{Zn}(\text{NCS})_4]^{2-}$  anion is tetrahedral; Zn–NCS–Zn bridging has been demonstrated in molten KNCS at 200 °C.

## 9 AQUEOUS SOLUTION CHEMISTRY

### 9.1 The $\text{Zn}^{2+}$ Aqua Cation

The  $\text{Zn}^{2+}$  cation appears to be six coordinate in water, from NMR ( $^1\text{H}$  peak areas), EXAFS (Extended X-ray Absorption Fine Structure), and Raman evidence, and six in methanol. X-ray and neutron diffraction studies indicate a Zn–O distance between 2.08 and 2.17 Å (cf. 2.08–2.14 Å in crystal hydrates). There is EXAFS evidence for a secondary hydration shell, containing about 12 water molecules at an average Zn–O distance of 4.1 Å.<sup>153</sup> Hydration numbers determined by methods other than NMR peak areas indicate values substantially larger than six, generally because both primary and secondary hydration shells are being monitored. The single-ion hydration enthalpy,  $\Delta H_{\text{hydr}}$ , of  $\text{Zn}^{2+}$  is  $-2044 \text{ kJ mol}^{-1}$  (relative to  $\Delta H_{\text{hydr}}(\text{H}^+) = -1091 \text{ kJ mol}^{-1}$ ). Full discussions of hydration of metal ions are available.<sup>154–157</sup> The  $\text{Zn}^{2+}\text{aq}$  ion is labile to water exchange ( $k > 5 \times 10^7 \text{ s}^{-1}$  at 298 K). There is some evidence that  $\text{Zn}^{2+}$  is only five coordinated in some mixed aqua ligand complexes.

$\text{Zn}^{2+}\text{aq}$  has very weak acidic properties – the most favored value for its  $\text{p}K_{\text{a}}$  is 8.96, though values ranging from 8 to over 10 have been reported from determinations by various physical techniques in a variety of media of different ionic strengths and containing different counterions.  $\text{ZnOH}^+\text{aq}$  is, like all hydroxo-metal ions, prone to polymerize; species such as  $[\text{Zn}_2(\text{OH})]^{3+}$ ,  $[\text{Zn}_2(\text{OH})_6]^{2-}$ , and  $[\text{Zn}_4(\text{OH})_4]^{4+}$  (cf. the well-established  $[\text{Pb}_4(\text{OH})_4]^{4+}$  and  $[\text{Ni}_4(\text{OH})_4]^{4+}$ ) have been postulated.

### 9.2 Stoichiometry, Structure, and Stability of Complexes in Solution

Table 3 collects together a number of stability constants (see *Stability Constants & their Determination*) for formation of monoligand complexes of  $\text{Zn}^{2+}$  in aqueous solution ( $\log_{10} K_1$ ), culled from several sources. Stability constants for no fewer than 81 bis-ligand complexes ( $\log_{10} \beta_2$ ) were conveniently collected together as long ago as 1959.<sup>158</sup> Much additional information on zinc complexes with ligands of biological importance is available.<sup>159</sup> Figures mapping the predominant species in solution over a range of pHs are available for 21  $\text{Zn}^{2+}$ -ligand systems.<sup>160</sup>

**Table 3** Stability constants ( $\log_{10} K_1$ ) for formation of a range of  $\text{Zn}^{2+}$  complexes, in aqueous solution at 298.2 K

| Group 15            |      | Group 16        |      |
|---------------------|------|-----------------|------|
| Azide               | 0.8  | Acetate         | 1.6  |
| Thiocyanate         | 0.9  | Thiosulphate    | 2.3  |
| Pyridine            | 1.0  | Phosphate       | 2.4  |
| Ammonia             | 2.3  | Oxalate         | 4.3  |
| Imidazole           | 2.6  | Citrate         | 5.0  |
| 2,2'-bipyridyl      | 5.1  | Acetylacetonate | 5.1  |
| Ethanediamine       | 5.9  | ATP             | 5.2  |
| 1,10-phenanthroline | 6.4  | Maltolate       | 5.6  |
| Group 15/16         |      | Group 17        |      |
| Glycine             | 5.0  | Fluoride        | 1.1  |
| Cysteine            | 9.2  | Chloride        | 0.5  |
| Penicillamine       | 9.5  | Bromide         | −0.6 |
| nta                 | 10.7 | Iodide          | −1.5 |
| EDTA                | 16.4 |                 |      |

Stability constant comparisons should be made with some caution, since the accuracies of some values may be no better than  $\pm 1$ , and experimental conditions (ionic strengths and the salts used to maintain them) are not identical for all systems. Nonetheless, the Table 3 values give some idea of relative stabilities for a range of ligands. The order of  $\log_{10} K_1$  values for the halide ions should be noted, for comparison of this set of values for  $\text{Zn}^{2+}$  with analogous values for  $\text{Cd}^{2+}$  and  $\text{Hg}^{2+}$  (Table 4) positions these cations according to the *Hard & Soft Acids and Bases* principle, with  $\text{Zn}^{2+}$  just on the hard side,  $\text{Cd}^{2+}$  just on the soft side, of the hard/soft border, and  $\text{Hg}^{2+}$  definitely soft.

$\text{Zn}^{2+}$  forms stable complexes with the group 14 donor ligand cyanide (mean  $\log_{10} K_1 = 5.1$ ). The cyanide ion is a good  $\sigma$ -donor (e.g. the  $\text{p}K_{\text{a}}$  of HCN is 9.4) and this may be the main factor in complex stabilization here. Interestingly, the  $\text{Zn}^{2+}$  ion does not form  $\pi$ -complexes (see *Coordination & Organometallic Chemistry: Principles*) with CO, NO, or alkenes although it is isoelectronic with  $\text{Ni}^0$ , archetypal in forming such species; possibly the 2+ charge on the  $\text{Zn}^{2+}$  ion is able to contract the d orbitals on the metal and reduce back donation (see *Back Bonding*) to the  $\pi$ -orbitals of the ligand.

Comparison of the stability constants for  $\text{Zn}^{2+}$  complexes with those for the preceding transition metal  $\text{M}^{2+}$  cations shows conformance to the Irving-Williams stability order (see *Irving-Williams Series*) ( $\text{Mn}^{2+} < \text{Fe}^{2+} < \text{Co}^{2+} < \text{Ni}^{2+} < \text{Cu}^{2+} \gg \text{Zn}^{2+}$ ) for essentially all ligands. As an example,

**Table 4** Comparison of stability constants ( $\log_{10} K_1$ ) for complex formation between  $\text{Zn}^{2+}$ ,  $\text{Cd}^{2+}$  and  $\text{Hg}^{2+}$  and halide ligands

|          | $\text{Zn}^{2+}$ | $\text{Cd}^{2+}$ | $\text{Hg}^{2+}$ |
|----------|------------------|------------------|------------------|
| Fluoride | 1.1              | 0.5              | 1.6              |
| Chloride | 0.5              | 1.8              | 6.7              |
| Bromide  | −0.6             | 1.9              | 9.4              |
| Iodide   | −1.5             | 2.0              | 12.9             |

**Table 5** Stepwise stability constants ( $\log_{10}K_n$ ) for formation of a selection of  $\text{Zn}^{2+}$  complexes, in aqueous solution at 298.2 K

|                | Monodentate ligands |         |             |       | Bidentate ligands |           |        |               |
|----------------|---------------------|---------|-------------|-------|-------------------|-----------|--------|---------------|
|                | Imidazole           | Ammonia | Thiocyanate | Azide | Oxalate           | Glycinate | Kojate | ethanediamine |
| $\log_{10}K_1$ | 2.6                 | 2.3     | 0.9         | 0.8   | $\log_{10}K_1$    | 4.3       | 5.0    | 5.0           |
| $\log_{10}K_2$ | 2.4                 | 2.5     | 0.7         | 0.5   |                   |           |        |               |
| $\log_{10}K_3$ | 2.2                 | 2.3     | 0.6         | 1.0   |                   |           |        |               |
| $\log_{10}K_4$ | 2.0                 | 2.2     | 0.3         | 0.6   | $\log_{10}K_2$    | 2.5       | 4.2    | 4.2           |
|                |                     |         |             |       | $\log_{10}K_3$    | 1.0       | 2.5    | 2.6           |
|                |                     |         |             |       |                   |           |        | 1.9           |

the values of  $\log_{10}K_1$  for 1,2-ethanediamine complexes are 2.7, 4.3, 5.9, 7.6, 10.7, and 5.9 respectively. Differences between stability constants for  $\text{Zn}^{2+}$  complexes and of their respective  $\text{Mg}^{2+}$  analogs are much larger for N-donor than for O-donor ligands. Indeed, a formula relating to the difference and the number of N- and O-donor sites on various ligands has been developed and used to determine the nature of the coordination sphere of the  $\text{Zn}^{2+}$  in cases where this is not clear-cut.<sup>161,162</sup>

Stability constants for  $\text{Zn}^{2+}$  complexes of the homologous dicarboxylate ligand series  $^-\text{O}_2\text{C}(\text{CH}_2)_n\text{CO}_2^-$  provide a good illustration of the decrease in stability as chelate ring size increases.  $\log_{10}K_1$  values for the oxalate ( $n = 0$ ), malonate ( $n = 1$ ), succinate ( $n = 2$ ), and glutarate ( $n = 3$ ) complexes are 5.0, 3.7, 2.5, and 2.0, quantifying the decrease in stability as the chelate ring increases in size from a five-membered to an eight-membered ring. The ligand series  $\text{NH}_3$  to en to dien to tren gives rise to modest chelate effects –  $\log_{10}\beta_2$  for  $[\text{Zn}(\text{NH}_3)_2]^{2+}$  is 4.8,  $\log_{10}K_1$  for  $[\text{Zn}(\text{en})_2]^{2+}$  5.9, while  $\log_{10}\beta_3$  for  $[\text{Zn}(\text{NH}_3)_3]^{2+}$  is 7.1,  $\log_{10}K_1$  for  $[\text{Zn}(\text{dien})]^{2+}$  8.9,<sup>163</sup> and  $\log_{10}\beta_4$  for  $[\text{Zn}(\text{NH}_3)_4]^{2+}$  is 9.3,  $\log_{10}K_1$  for  $[\text{Zn}(\text{tren})]^{2+}$  14.5.

$\text{Zn}^{2+}$  forms stable complexes with the standard tetraaza-macrocyclic ligands, though the variation of stability constants with ring size is unusually small –  $\log_{10}K_1$  values decrease from 16.2 for the 12-membered ring through 15.6 and 15.5 to 15.0 for the 15-membered ring ligand.<sup>164</sup> Studies on the complexing of zinc with 1,3,5-*cis,cis*-triaminocyclohexane (L) show that the  $[\text{ZnL}]^{2+}$  complex formed is less stable than that formed with analogous linear triamines such as 3,3'-diaminodipropylamine (in the presence of excess of ligand only the hydroxo-ion  $[\text{ZnL}(\text{OH})]^+$  is formed in both cases). However, a significant macrocyclic effect is evident in the large stability constant observed for the  $[\text{ZnL}]^{2+}$  complex of the cyclic triamine 1,4,7-triazacyclononane. Chelate and macrocyclic effects ( $K$ ,  $\Delta H$ , and  $\Delta S$ ), effects of ligand N-alkylation, and stability comparisons with selected  $\text{M}^{2+}$  ions, have been conveniently documented, for edta and for some tetra-aza macrocyclic ligands.<sup>165</sup> A comprehensive survey of thermodynamic, and kinetic, data for macrocyclic ligand interaction with cations, including extensive data on zinc, is available<sup>166</sup> (see also **Macrocyclic Ligands**). Macrocyclic complexes sometimes have unexpected properties; for example, zinc complexes with the tetraazacycloalkanes [14]aneN<sub>4</sub>

and [15]aneN<sub>4</sub> reversibly take up  $\text{CO}_2$  in basic alcoholic solutions to form monoalkyl carbonates.<sup>167</sup>

Trends in stepwise stability constants (successive formation constants); (see **Stability Constants & their Determination**) for  $\text{Zn}^{2+}$  complexes (Table 5) are often irregular, differing markedly from the normal trend of  $K_n$  decreasing as  $n$  increases. This has been known for at least sixty years – Jannik Bjerrum, in his seminal study of metal-ammine complexes carried out in about 1940, documented an irregular variation of  $K_n$  with  $n$  for this classic series. Table 5 documents this behavior for the amines, and shows irregular behavior also for azide and for 1,2-ethanediamine. Only the imidazole, thiocyanate, and oxalate data in Table 5 show normal trends. Irregularities are all ascribed to changes between octahedral and tetrahedral geometries, as for example, for the unexpectedly large drop from  $K_2$  to  $K_3$  for 1,2-ethanediamine, and calculations have been made of the proportions of tetrahedral and octahedral species in several systems.<sup>168</sup> For penicillamine,  $K_2 > K_1$ , which unusual behavior has been ascribed to a change from tridentate to bidentate coordination.

In order to probe the immediate coordination sphere of the metal in zinc complexes in solution, especially to attempt to solve the tetrahedral versus octahedral uncertainties outlined above, it is possible to have recourse to a number of physical techniques, including Raman spectroscopy, NMR, X-ray and neutron diffraction,<sup>169</sup> and X-ray scattering (EXAFS). However, the complex equilibria present in electrolytically produced supersaturated solutions of zinc(II) in aqueous KOH show how different techniques can lead to different results in identifying the species present in what appears at first sight to be a simple system. Light scattering and NMR techniques<sup>170</sup> indicate the excess of zinc to be present as a solute, rather than a colloid, and the predominant species appears to be  $[\text{Zn}(\text{OH})_4]^{2-}$ . However, Raman and potentiometric studies<sup>171</sup> indicate that initially quasicolloidal particles, based on  $\text{Zn}(\text{OH})_2$  and hydrating water molecules, are present. These undergo a first-order decay to yield a solution containing the species  $[\text{Zn}(\text{OH})_2(\text{H}_2\text{O})_2]$ ,  $[\text{Zn}(\text{OH})_3(\text{H}_2\text{O})]^-$ , and  $[\text{Zn}(\text{OH})_4]^{2-}$ , the actual composition depending on the concentration. The noncolloidal species in this system appear to be tetrahedral rather than octahedral.

X-ray scattering measurements, Raman, and IR spectroscopy on aqueous solutions containing  $\text{Zn}^{2+}$  and  $\text{Br}^-$  ions show that the highest complex formed is tetrahedral

$[\text{ZnBr}_4]^{2-}$ ; pyramidal  $[\text{ZnBr}_3]^-$  is also formed but there is no evidence of Zn–Br–Zn bridges.<sup>172</sup> Studies of  $\text{Zn}^{2+}/\text{Cl}^-$  solutions have provided conflicting results, with X-ray studies indicating  $[\text{ZnCl}_4]^{2-}$ , other techniques indicating octahedral geometry, that is,  $[\text{ZnCl}_4(\text{H}_2\text{O})_2]^{2-}$ . The apparent disagreement is almost certainly due to the different concentration ranges pertaining to the techniques used – the X-ray methods require concentrated solutions, the other techniques less concentrated media. Indeed neutron diffraction suggests  $[\text{ZnCl}_4(\text{H}_2\text{O})_2]^{2-}$  in 1 or 2 M  $\text{ZnCl}_2$ ,  $[\text{ZnCl}_4]^{2-}$  in more concentrated solutions. Diffraction results are consistent with tetrahedral  $[\text{Zn}(\text{NH}_3)_4]^{2+}$  (Zn–N = 2.03 Å) and with both tetrahedral  $[\text{Zn}(\text{en})_2]^{2+}$  (Zn–N = 2.13 Å) and octahedral  $[\text{Zn}(\text{en})_3]^{2+}$  (Zn–N = 2.28 Å), depending on conditions.<sup>173</sup>

Complexes of the Group 12 metal cations with thiocyanate provide data on the relative affinities of these ions for N- or S-donors. X-ray scattering studies indicate the existence in solution of  $[\text{Zn}(\text{NCS})_4]^{2-}$ ,  $[\text{Cd}(\text{NCS})_2(\text{SCN})_2]^{2-}$ , and  $[\text{Hg}(\text{SCN})_4]^{2-}$ , all tetrahedral, consistent with the ‘hard’ to ‘soft’ trend of the respective  $\text{M}^{2+}$  cations. A Raman study of zinc(II) coordination in aqueous thiocyanate solutions<sup>174</sup> showed that bonding to the zinc is totally in the Zn–NCS mode and the results were consistent with the presence of all four  $[\text{Zn}(\text{NCS})_{1-4}]^{n\pm}$  species. The two lower species are probably octahedrally coordinated, the remaining coordination sites being occupied by water molecules; higher species are probably tetrahedrally coordinated. No bridging thiocyanate is observed. This contrasts with evidence from the Raman spectrum of coordinated zinc in KSCN at 200 °C, which shows the presence of tetrahedral  $[\text{Zn}(\text{NCS})_4]^{2-}$  species, somewhat distorted by polymerization, and bands owing to Zn–NCS–Zn bridges are also observed. *Linkage Isomerism* is also present owing to both Zn–NCS and Zn–SCN bonding modes.

Sometimes coordination can affect the behavior of another ligand in the coordination shell of the metal and this is well illustrated by acidities of ternary aqua-ligand- $\text{Zn}^{2+}$  complexes. Quadridentate 1,5-diazocyclooctane-*N,N'*-diacetic acid,  $\text{H}_2\text{L}$ , forms  $[\text{Zn}(\text{L})(\text{H}_2\text{O})]$ , the  $\text{pK}_a$  of whose coordinated  $\text{H}_2\text{O}$  (8.6) is slightly lower than that of  $\text{Zn}^{2+}\text{aq}$  (9.0), and considerably lower than that of the coordinated  $\text{H}_2\text{O}$  (10.5) in the octahedral complex formed by ethylenediaminediacetate. Increased acidity of coordinated  $\text{H}_2\text{O}$  with decreasing coordination number has also been observed in other complexes such as  $[\text{Zn}(\text{Me}_6\text{tren})(\text{H}_2\text{O})]^{2+}$ ,  $[\text{Zn}([12]\text{aneN}_3)(\text{H}_2\text{O})]^{2+}$  ( $\text{pK}_a = 7.3$ ) and  $[\text{Zn}(\text{cyclen})(\text{H}_2\text{O})]$  ( $\text{pK}_a = 7.9$ ).<sup>175</sup> This has been attributed, at least in part, to the hydrophobic environment provided by the methyl and methylene groups. This finding has some implications for the role of the Zn–OH<sub>2</sub>/OH species in the zinc metalloenzyme carbonic anhydrase (see *Zinc Enzymes*), where this unit is contained in a site of low-coordination number and a small movement can place it in an environment of decreased polarity. Such marked increase in the acidity of coordinated water has important implications, especially for biological systems: essentially the metal ion-hydroxy complex provides an efficient nucleophile at neutral

pH<sup>176</sup> (see also *Zinc Enzymes*). Model studies with metal ions, mainly zinc(II), as Lewis acid catalysts have been reviewed.<sup>177</sup>

Binding constants determined for ternary complex formation between capped and uncapped zinc porphyrins and small molecules such as imidazole and (substituted) pyridine<sup>178</sup> contribute to the understanding of capped zinc porphyrins in molecular recognition,<sup>179</sup> to which topic ternary zinc-cyclen complexes are also relevant.<sup>180</sup>

### 9.3 Kinetics and Mechanisms

Complex formation between  $\text{Zn}^{2+}$  and most monodentate and simple chelating ligands is rapid, with  $k_f \sim 10^7 \text{ M}^{-1} \text{ s}^{-1}$  at 298 K.<sup>181</sup> However, there are exceptions where the steric requirements of the ligand are particularly stringent. Reactions of  $\text{Zn}^{2+}\text{aq}$  with tetraazamacrocycles are slow – rate laws are complicated, but half-lives are of the order of a second. Formation of the  $\text{Zn}^{2+}$  complex of the *Quadridentate Ligand* 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (L), which is a five-coordinated species  $[\text{ZnL}(\text{H}_2\text{O})]^{2+}$ , is probably slow owing to the requirement for conformational change on complexation. Dissociation of this complex is acid catalyzed (see *Acid Catalyzed Reaction*), with this five-coordinate species more labile than four- or six-coordinated complexes, a feature that could be relevant to the biological function of zinc.<sup>182</sup> Other cases of slow complex formation are provided by several porphyrins and by the catenand ligand (10). Half-lives for incorporation of zinc into porphyrins are typically of the order of a second. Reaction with the catenand is biphasic (see *Biphasic Process*); the first step (overall second order) probably represents binding of the ligand to one of the chelating subunits of (10). The second step, which is first order, is very slow ( $k \ll 1 \text{ s}^{-1}$ ) and could well correspond to the sliding motion of one ring within the other while the second phenanthroline unit attempts to seek out and bind the zinc center.<sup>183</sup> Metal-for-metal replacement in porphyrin complexes can, however, be quite rapid, as in the case of  $\text{Zn}^{2+}$  with  $\text{Hg}(\text{tpp})$  in pyridine, where no less than seven isosbestic points are observed.<sup>184</sup> There is rapid equilibration between  $\text{Zn}^{2+}$  and  $\text{Pb}^{2+}$  at the metal-binding site of zinc fingers despite steric constraints;<sup>185</sup> the rate constant for reaction of a typical *Zinc Finger* peptide with  $\text{Zn}^{2+}\text{aq}$  has been estimated as  $2.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ .<sup>186</sup>

There is a marked contrast between zinc and cadmium in the context of complexing of the 2+ ions with bipy, studied by high-pressure stopped-flow. There is a striking difference between the two elements, with  $\text{Zn}^{2+}$  reacting progressively more slowly with bipy as pressure increases,  $\text{Cd}^{2+}$  more rapidly. The *Activation Volume* ( $\Delta V^\ddagger$ ) for the zinc reaction is  $+7.1 \text{ cm}^3 \text{ mol}^{-1}$  whereas for cadmium the value is  $-5.5 \text{ cm}^3 \text{ mol}^{-1}$ . These values suggest that the substitutions are  $I_d$  and  $I_a$  in character respectively.<sup>187</sup>  $\Delta V^\ddagger$  values for the reverse, dissociation, reaction and  $\Delta S^\ddagger$  values for formation and for dissociation, are all consistent with this assignment of mechanism. Positive activation volumes for a few other substitution reactions at  $\text{Zn}^{2+}\text{aq}$ <sup>188</sup> also indicate  $I_d$  mechanisms, as proposed many years ago in discussions of ultrasonic data on complex formation from  $\text{Zn}^{2+}\text{aq}$ .

Metal ion promoted reactions are important –  $\text{Zn}^{2+}$  – catalyses of hydrolysis of a range of organic substrates, for example, phosphate and carboxylate esters and Schiff bases, have recently been reviewed,<sup>189</sup> as has their relevance to biological catalysis, particularly of reactions of phosphates.<sup>190</sup>

Kinetic patterns and parameters, and mechanisms, of these and other reactions involving zinc complexes have been detailed and reviewed.<sup>191,192</sup>

## 1 INTRODUCTION

The first organometallic compounds of zinc, namely, ethylzinc iodide (EtZnI) and diethylzinc (Et<sub>2</sub>Zn), were

prepared by Sir Edward Frankland in 1849<sup>1–3</sup> when he attempted the preparation of 'ethyl radical'. Even if these two species were not the first organometallic derivatives to be prepared (cacodyl compounds and Zeise's salt (*see Zeise's Salt*) were discovered in 1760 and 1827, respectively), the work of Frankland is now recognized as the beginning of modern organometallic chemistry. He recognized very early the synthetic utility of EtZnI and Et<sub>2</sub>Zn, and devoted his career to studying their properties and to preparing other organic compounds of tin, mercury, and arsenic. Owing to their low reactivity, a result of the high covalent character of the zinc–carbon bond and the low Lewis acidity (*see Lewis Acids & Bases*) of Zn<sup>II</sup>, the organozinc reagents were replaced at the beginning of the twentieth century by the more reactive Grignard and organolithium reagents. For more than half a century, their application to organic synthesis was limited to specific reactions, mostly cyclopropanation and aldol reactions. However, in recent years it was found that the low reactivity of organozinc species makes them highly tolerant to a wide range of functional groups and allows good regio- and enantioselectivities in their transformations.

Furthermore, organozinc derivatives readily form complexes with electron-donating ligands as a result of the electron-deficient character of zinc. In spite of the early knowledge of this property, it was only after the 1960s that this subject became the source of extensive investigations and led to the development of an extremely rich coordination chemistry.

In the past few decades, these features have stimulated a growing interest for this area of organometallic chemistry and nowadays the organozinc compounds play a very important role in organic, organometallic, and inorganic chemistry. Their low toxicity, excellent functional group tolerance, chemoselectivity, and stereoselectivity make them ideal reagents for the building of complex molecules bearing polyfunctional groups.

Over the years, several reviews dealing with different aspects of the organometallic chemistry of zinc have been published.<sup>4,5</sup>

## 2 DIORGANOZINC COMPOUNDS

### 2.1 Preparation

The different routes for the preparation of organozinc compounds are summarized in Scheme 1. Detailed experimental protocols including important tips can be found in references 6 and 7. In the last decade, this subject was included in several reviews dealing with the applications of polyfunctional organozinc compounds in organic synthesis.<sup>8–10</sup>

Scheme 1

### 2.1.1 Direct Reaction of Zn with Alkyl Halides

This method was originally used by Frankland to prepare diethylzinc. It is described as an oxidative insertion (*see Insertion*) of zinc metal inside the carbon-halogen bond of an organic halide. The initial product of the reaction is an alkylzinc halide derivative ( $\text{RZnX}$ ), from which the dialkylzinc compound ( $\text{R}_2\text{Zn}$ ) is formed as the Schlenk-type equilibrium establishes (equations 1 and 2).

The ideal alkyl halide substrates are the alkyl iodides and usually the reaction requires the zinc to be activated by forming an alloy (*see Alloys*) with a metal such as copper, sodium, or mercury. Finely divided forms of zinc (powder or dust), alone or previously treated with copper or sodium acetate, are also very effective.

Another procedure for the preparation of very active zinc uses the ‘metal atom’ approach in which zinc-metal vapor is coprecipitated with an ethereal solvent.<sup>11</sup> The unstable bis(trifluorosilyl)zinc and bis(trifluoromethyl)zinc have been prepared by cocondensing Zn atoms with  $\cdot\text{SiF}_3$  radicals (*see Radicals*) and  $\cdot\text{CF}_3$  radicals, respectively (generated by low-temperature radio-frequency glow discharge or plasma of hexafluoroethane or hexafluorodisilane).<sup>12</sup>

The Riecke zinc,<sup>13</sup> obtained by reduction of a zinc halide with sodium or potassium in THF, is commonly used for the

preparation of simple or functionalized organozinc compounds and allows the use of less reactive alkyl halide reagents like alkyl bromides. The reaction of this very active form of zinc with organic bromides was shown to be strongly dependent on the structure of the organic moiety.<sup>14</sup> The results also support the presence of radicals (*see Radicals*) in the reaction and suggest a mechanism in which electron transfer (*see Electron Transfer Reactions: Theory*) (ET) is the rate-determining step. In the reaction with alkyl bromides, the ET has an important component of inner sphere, whereas in the reaction with aryl halides there is a participation of aryl halide radical anions as intermediates. A classification of the organic bromides, depending on the nature of the organic group and attending to their relative reactivity, can be summarized by the diagram presented in Figure 1. The less reactive vinyl bromides are found in one extreme and the most reactive benzylic bromides in the other.

In the past years, numerous modifications for zinc activation have been developed, not only to increase the reaction efficiency, but also to allow the use of less reactive and inexpensive organic halides such as organic chlorides.

### 2.1.2 Iodine–Zinc Exchange

Diorganozinc reagents can be prepared efficiently by an iodine–zinc exchange reaction<sup>15</sup> between the appropriate alkyl halide and an excess of  $\text{Et}_2\text{Zn}$  or  $i\text{-Pr}_2\text{Zn}$  (equation 3). This method is suitable for primary and secondary alkyl iodides and requires catalytic amounts of a  $\text{Cu}^{\text{I}}$  salt. The reaction conditions with  $i\text{-Pr}_2\text{Zn}$  (25 °C, 1 h) are considerably milder than those used with  $\text{Et}_2\text{Zn}$  (50 °C) and allow the preparation of complex diorganozinc species in good yields. A possible mechanism for the catalyzed reaction with  $\text{Cu}^{\text{I}}$  is given in Scheme 2.<sup>8</sup>

Other transition metals (*see Transition Metals*) such as  $\text{PdCl}_2(\text{dppf})$  and  $\text{Ni}(\text{acac})_2$ <sup>16,17</sup> catalyze the reaction but lead to alkylzinc iodides instead of dialkylzinc compounds.

Recently, it was shown that the exchange reaction can be photochemically (*see Photochemistry*) induced by irradiating at  $\lambda \geq 280\text{ nm}$  the reaction mixture of an alkyl iodide and 0.5 equiv of  $\text{R}_2\text{Zn}$  ( $\text{R} = \text{Et}$  or  $i\text{-Pr}$ ) (equation 4).<sup>18</sup>

Figure 1 Relative dimensionless rates for  $\text{RBr} + \text{Zn}^* \rightarrow \text{RZnBr}$

Scheme 2

In these conditions, excess of  $\text{R}_2\text{Zn}$  and the catalyst (transition metal) are not required. In addition, when a solution of an alkyl iodide is mixed with 1 equiv of  $\text{R}_2\text{Zn}$  the mixed diorganozinc compounds ( $\text{R-Zn-R}'$ ) are obtained (equation 5). This reaction takes place only between dialkylzincs and alkyl iodides; however, in comparison with the few other methods described for the preparation of mixed diorganozincs, this procedure represents a fantastic enhancement for alkyl group exchange ( $\text{R-Zn-R}'$ ).<sup>19,20</sup>

### 2.1.3 Alkylation of Zinc Salts

This method, presented in equation (6), involves the alkylation of zinc salts, usually zinc halides or zinc acetate. The alkylating agents are typically Grignard reagents or organolithium (see *Alkali Metals: Organometallic Chemistry*) reagents in an ethereal solvent, but trialkylaluminum or zirconocene reagents can also be used. For example the preparation of dimethyl- and diethylzinc is described by the

reaction of trimethyl- and triethylaluminum with zinc acetate<sup>21</sup> (equation 7). This procedure is useful for the preparation of simple dialkylzinc but the high reactivity of organolithium or magnesium (see *Beryllium & Magnesium: Organometallic Chemistry*) reagents precludes the synthesis of zinc derivatives containing functional groups, although the use of low temperature can in some cases overcome this problem.<sup>22</sup>

It is worth mentioning here that disupersilylmetals ( $t\text{-Bu}_3\text{Si}$ )<sub>2</sub>M, supersilylmetal halides ( $t\text{-Bu}_3\text{Si}$ )MX and bis(disupersilyl)silylmetals [( $t\text{-Bu}_3\text{Si}$ )<sub>2</sub>SiH]<sub>2</sub>M (M = Zn, Cd, Hg; X = Cl, Br) have been recently prepared by reaction of the corresponding silyl-sodium salts with metal dihalides in 1:1 or 2:1 ratio, and could be fully characterized<sup>23,24</sup> (Scheme 3). The disupersilylzinc compound was found to react with  $\text{BiCl}_3$  or  $\text{BBr}_3$  to give the corresponding supersilylzinc halide ( $t\text{-Bu}_3\text{Si}$ )ZnX.

### 2.1.4 Boron–Zinc Exchange

The first boron–zinc exchange reported in the literature was the reaction of dimethylzinc with triethylborane to produce diethyl zinc<sup>25</sup> (equation 8). The driving force of the reaction is the formation of stable dialkylzinc compounds, and in some cases the formation of volatile organoboranes such as  $\text{BMe}_3$  (bp =  $-22^\circ\text{C}$ ). Primary dialkyl and benzylic organozinc compounds are successfully prepared when  $\text{Me}_2\text{Zn}$  or  $\text{Et}_2\text{Zn}$  are used as reagents,<sup>26</sup> but the B–Zn exchange is usually slow with hindered secondary alkylboranes. However,  $i\text{-Pr}_2\text{Zn}$  has been found to undergo rapid exchange with both primary and secondary substrates, leading to the preparation of secondary dialkylzincs. An important feature of the exchange reaction is that retention of configuration was observed with several

Scheme 3

systems at low temperature<sup>27</sup> ( $-10^{\circ}\text{C}$ ).

The reaction conditions are significantly mild ( $0^{\circ}\text{C}$ ) and allow the presence of a number of sensitive functional groups. Although this procedure presented limited applications when it was discovered, during the last years it became one of the most versatile preparations of polyfunctional diorganozinc species; a consequence of both its high tolerance towards functional groups and its high stereoselectivity.<sup>8</sup>

A recent theoretical study has shown that the B–Zn exchange proceeds with a low activation energy and could involve two intermediates (Figure 2), the particularly unusual bonding structures of which would be responsible for the retention of configuration.<sup>28</sup>

### 2.1.5 Transmetallation with Mercury

In 1864, Frankland discovered the transmetallation reaction between diorganomercurials and zinc metal<sup>29</sup> (equation 9). It is generally applicable when the organomercury compounds are available and when it is necessary to prepare absolute salt free diorganozinc compounds.

Usually the reaction requires an excess of zinc metal, a few hours in refluxing toluene, and can eventually be catalyzed with small amounts of zinc salts. A modification of this method, employing dimethyl zinc instead of zinc metal, has been used to prepare a stable complex of bis(trifluoromethyl)zinc with pyridine<sup>30,31</sup> (equation 10).

## 2.2 Properties of Diorganozinc Compounds

Depending on the nature of the alkyl group, simple dialkylzinc compounds can be mobile liquids or low-melting solids (Table 1). They are all colorless and completely miscible with common nonprotic solvents. With polar (*see Polar*

*Compounds*) organic solvents containing electron-donating atoms, they form soluble complexes. However, in pure form or in hydrocarbon solvents, they exist as monomers, since association via alkyl bridges doesn't occur with zinc. Dialkylzinc compounds are all very susceptible to oxygen and moisture attack; in consequence all manipulations must be performed in an inert atmosphere. The derivatives of low-molecular weight are spontaneously flammable on contact with air, producing a fume of  $\text{ZnO}$ , while higher molecular weight derivatives are less sensitive. It is worth noting that both  $[(\text{Me}_3\text{Si})_3\text{C}]_2\text{Zn}$  and the closely related cyclic derivative  $[-\text{C}(\text{SiMe}_3)_2\text{SiMe}_2\text{CH}_2\text{CH}_2\text{Me}_2\text{Si}(\text{Me}_3\text{Si})_2\text{C}-]_n\text{Zn}$  are remarkably resistant towards water or electrophilic (*see Electrophile*) reagents.<sup>32,33</sup> The thermal stability of dialkylzinc compounds also varies with the nature of the alkyl group; it decreases with the increase of the chain length and the substitution degree on the  $\alpha$ -carbon atom. Dimethylzinc is stable at room temperature, whereas di-*iso*-propyl- and di-*tert*-butylzinc decompose at  $0^{\circ}\text{C}$  and should be stored at dry ice temperature. The mean Zn–C bond dissociation energies ( $\bar{D}$ ) (*see Bond Dissociation Energy*) have been determined by calorimetric studies for some of the compounds listed in Table 1.<sup>34</sup> In the particular case of  $\text{Me}_2\text{Zn}$ , the first- and second-bond dissociation energies have also been calculated<sup>35</sup> ( $D_1 = 266 \pm 6 \text{ kJ mol}^{-1}$ ;  $D_2 = 102 \pm 17 \text{ kJ mol}^{-1}$ ).

## 2.3 Structure of Diorganozinc Compounds

### 2.3.1 Dialkylzinc Compounds

Two-coordinate organozinc compounds, containing saturated alkyl or aryl groups (with the exception of  $\text{Ph}_2\text{Zn}$ ), are invariably monomeric with linear geometries at the Zn atom. Therefore they are nonpolar, and most of those whose structures have been determined bear this out<sup>36</sup> (Table 2). Several studies of the vibrational spectrum of  $\text{Me}_2\text{Zn}$  showed unequivocally that the valence angle C–Zn–C is  $180^{\circ}$  and that the methyl groups undergo virtually free internal rotation. The

**Table 2** C–Zn–C angle and C–Zn bond length of some dialkylzinc compounds

|                                                                                                | C–Zn–C (°) | C–Zn (Å)                                |

<sup>a</sup>Data determined by gas-phase electron diffraction.<sup>38</sup> <sup>b</sup>Data determined by X-ray crystallography.<sup>36,39</sup>

molecular structures of dimethyl-, diethyl- and dipropylzinc, determined by gas-phase electron diffraction,<sup>37</sup> display the Zn–C bond distances listed in Table 2.

This observation contrasts dramatically with the property of the pretransition metals, magnesium and beryllium (*see Beryllium & Magnesium: Organometallic Chemistry*), to adopt polymeric structures with bridging alkyl groups and four-coordinate metal centers. The low electronegativity (*see Electronegativity*) difference between zinc and carbon ( $\chi_{\text{Zn}} = 1.7$ ;  $\chi_{\text{C}} = 2.5$ ) leads to a low polarity (*see Polar Bonds*) of the Zn–C bond which associated with the large size of the zinc atom are thought to be responsible for the monomeric nature of diorganozinc compounds. However, an NMR study of methyl group exchange between dimethylzinc and dimethylcadmium shows that bridging alkyl groups between zinc and cadmium may be possible at least in transition states.<sup>40,41</sup>

The only exception to linear monomeric structure is diphenylzinc, which presents a dimeric structure in solid state by virtue of an interaction between the ipso carbon of one  $\sigma$ -bound phenyl group and the zinc center of another Ph<sub>2</sub>Zn unit.<sup>38</sup> The bond lengths between zinc and the terminal phenyl groups are as expected [1.941(4) and 1.951(5) Å]. Nevertheless, the two phenyl groups bridge the two metal centers in an asymmetric fashion, with two short [2.006(5) and 2.016(3) Å] and two long [2.442(4) and 2.364(5) Å] Zn–C bonds (Figure 3). Thus, this interaction was best pictured as an electrophilic attack on the zinc phenyl group by an adjacent Lewis acidic (*see Lewis Acids & Bases*) center than as an

**Figure 3** Structure of PhZn( $\mu$ -Ph)<sub>2</sub>ZnPh

association via three-center, two-electron (*see Three-center Bond*) alkyl bridges. The fact that diphenyl zinc is monomeric in hexane solution supports this suggestion.

In contrast to (Ph<sub>2</sub>Zn)<sub>2</sub>, both bis(pentafluorophenyl)zinc<sup>42</sup> and bis[2,4,6-tris(trifluoromethyl)phenyl]zinc<sup>43</sup> have a two-coordinate monomeric solid-state structure approaching linearity, which is certainly a result of electronic and steric (*see Steric Effect*) properties of the *ortho* substituents (Figure 4). In the crystal structure of both compounds, the aromatic rings are almost orthogonal to one another. This special situation alleviates intramolecular (*see Intramolecular*) steric interactions and allows intramolecular stacking interactions between rings on adjacent molecules.

It is worth mentioning that the molecular structures of different bis(disubstituted)silylmethylmetals [(*t*-Bu<sub>3</sub>Si)<sub>2</sub>HSi]<sub>2</sub>M, determined by X-ray analysis,<sup>24</sup> show nonlinear frameworks Si–M–Si (M = Zn, Cd, Hg) (Figure 5). This feature, which is unprecedented for homoleptic (*see Homoleptic Compound*) dicoordinate zinc compounds, is believed to arise from van der Waals attractions between methyl groups of the supersilyl substituents. In contrast, supersilylmethylmetal derivatives of general formula (*t*-Bu<sub>3</sub>Si)<sub>2</sub>M (M = Zn, Cd, Hg), present a common linear geometry at the metal center with a Si–M–Si angle of 180°. The Si–Zn bond lengths vary from 2.384 Å in (*t*-Bu<sub>3</sub>Si)<sub>2</sub>Zn to 2.449 Å in [(*t*-Bu<sub>3</sub>Si)<sub>2</sub>HSi]<sub>2</sub>Zn.

### 2.3.2 Unsaturated Dialkylzinc Compounds

The situation is different when diorganozinc species bear unsaturated moieties. Although dialkenylzinc compounds such as divinylzinc are monomeric in benzene solution, they have higher melting and boiling points than their saturated analogues, indicating larger intermolecular interactions in

**Figure 4** Structure of [2,4,6-(CF<sub>3</sub>)<sub>3</sub>C<sub>6</sub>H<sub>2</sub>]<sub>2</sub>Zn and (C<sub>6</sub>F<sub>5</sub>)<sub>2</sub>Zn

**Figure 5** Structure of supersilylzinc  $(t\text{-Bu}_3\text{Si})_2\text{Zn}$  and bis(disupersilyl)silylzinc compounds  $[(t\text{-Bu}_3\text{Si})_2\text{HSi}]_2\text{Zn}$

solid and liquid phases. Directly bounded alkynyl groups are believed to be the only ones that can form stable bridges between zinc atoms (Figure 6). So far there is no structural determination of this type of compounds, but their associative nature is reflected by their high melting points and low solubility in nonpolar solvents.<sup>44</sup>

From  $^1\text{H}$  NMR studies, it was shown that diallylzinc compounds undergo fluxional processes between all possible isomeric  $\sigma$ -bonded (see  $\sigma$ -Bond) allylic forms<sup>45</sup> (Scheme 4).

### 2.3.3 Cyclopentadienylzinc Compounds (See Cyclopentadienyl)

While dicyclopentadienyl compounds of transition metals (see *Transition Metals*) typically have a ferrocene-like (see *Ferrocene*) sandwich structure, the electron-deficient cyclopentadienides of the main group metals tend to form polymers with bridging cyclopentadienyl (Cp) groups.<sup>46</sup> Although exceptions are known, the tendency is rather consistent. The element zinc, owing to its borderline position between transition metals and main group metals, presents a variety of coordination (see *Coordination Numbers & Geometries*) modes with the Cp anion.

The structure of  $\text{CpZnCH}_3$  has been determined in both solid state and gas phase.<sup>47,48</sup> In the gas phase, the compound

**Figure 6** Bridging alkynyl groups between zinc atoms

**Scheme 4**

is monomeric with  $C_{5v}$  symmetry. The Cp ligand features  $\eta^5$ -coordination to zinc, thereby creating an 18-electron (see *Eighteen Electron Compounds*) shell for the zinc atom (Figure 7). However, in crystalline state, the compound exists as a polymer with Cp ligands bridging zinc centers. The hapticity (see *Hapticity*) of the Cp groups varies from two to three (Figure 8).

A related polymeric structure, somewhat more complex, occurs in the solid state of  $\text{Cp}_2\text{Zn}$ .<sup>49</sup> This structure consists of infinite chains of zinc atoms with bridging Cp groups and, in addition, each zinc atom carries a terminal Cp group (Figure 9). Neither the terminal nor the bridging Cp groups are bounded to zinc in a purely  $\eta^1$ -fashion; the bonding situation is best described as ' $\eta^{2.5}$ '. Owing to its low thermal stability, this compound could not be studied in the gas phase.

Zinconocenes possessing Cp ligands of different electronic and steric properties (see *Steric Effect*) have been synthesized and structurally characterized. Whereas  $\text{Cp}_2\text{Zn}$  is polymeric in the solid state, replacement of hydrogen atoms by methyl or isopropyl groups lead to compounds which exhibit a 'slipped-sandwich' (see *Slip Processes in Ligands*) motif with both  $\eta^1$ - and  $\eta^5$ -Cp ligands. For example, the structure of bis(pentamethylcyclopentadienyl)Zn ( $\text{Cp}_2^*\text{Zn}$ ) determined in gas phase<sup>50,51</sup> and in crystalline state<sup>52</sup> is presented in Figure 10. The  $^1\text{H}$  NMR spectra at room temperature of this derivative shows only one set of resonances, indicating a rapid haptotropic exchange, or 'ring-slippage', between  $\eta^1$ - and  $\eta^5$ -coordination (Figure 11). Comparable situations, showing different degree of 'ring-slippage', have been observed in gas phase for  $(\text{C}_5\text{H}_4\text{SiMe}_3)_2\text{Zn}$ , and by X-Ray diffraction

**Figure 7** Structure of monomeric  $\text{CpZnMe}$  in the gas phase

**Figure 8** Part of the polymeric structure of  $\text{CpZnMe}$  in the solid state

**Figure 9** Schematic representation of the chain structure of  $\text{Cp}_2\text{Zn}$

for  $(\text{C}_5\text{Me}_4\text{Ph})_2\text{Zn}$  and  $(\text{C}_5\text{H}-i\text{-Pr}_4)_2\text{Zn}$ .<sup>52,53</sup> Compared to the magnesium (see *Beryllium & Magnesium: Organometallic Chemistry*) derivatives  $\eta^5\text{-Cp}_2\text{Mg}$  or  $\eta^5\text{-Cp}_2^*\text{Mg}$  of regular sandwich (see *Sandwich Compound*) structures, zinc metallocenes are highly sensitive on contact with air. This sensitivity of slipped-sandwich compounds can be explained by a less effective encapsulation of the metal center.

A new bonding mode between the Cp ring and Zn has been observed for  $[\text{CpZn}(\mu\text{-Cp})\{\mu\text{-N}(\text{TMS})_2\}\text{ZnCp}]$ .<sup>54</sup> This compound is the first example of a Cp group that bridges between nonbonded metal atoms located on the same side of the ring plane (Figure 12).

The nature of the binding mode between zinc and three different (dialkylamino)ethylcyclopentadienyl ligands has been studied.<sup>55</sup> X-ray structural determinations of such derivatives show that the Cp rings are bound to the zinc centers in a  $\eta^1$  fashion and via their amine groups, thus forming stable six-membered metallacycle (Figure 13). Similarly, the acyclic pentadienyl ligands in  $(2,4\text{-}t\text{-Bu}_2\text{C}_5\text{H}_5)_2\text{Zn}$  and in the complex  $(\text{C}_5\text{H}_7)\text{ZnCl}\cdot\text{TMEDA}$  only exhibit  $\eta^1$  coordination.<sup>56,57</sup>

**Figure 10** Molecular structure of  $(\text{Me}_5\text{C}_5)_2\text{Zn}$  in the gas phase

**Figure 11** "Ring-slippage" in zinconocene compounds

**Figure 12** Structure of  $\text{Cp}_3\text{Zn}_2\text{N}(\text{SiMe}_3)_2$

**Figure 13** Structure of (dialkylamino)ethylcyclopentadienylzinc derivatives

**Figure 14** Structure of  $[(\text{Me}_3\text{Si})_3\text{C-Zn}]_2(\mu\text{-Cl})(\mu\text{-Pyr}^*)$

Interestingly, the anion 2,5-di(*tert*-butyl)pyrrolide  $[2,5\text{-}(t\text{-Bu})_2\text{C}_4\text{H}_2\text{N}]^-$  ( $\text{Pyr}^*$ ), which is isoelectronic (see *Isoelectronic*) with the Cp anion, reacts with tris(trimethylsilyl)methylzinc chloride to give the very stable bis[tris(trimethylsilyl)methylzinc] chloride 2,5-di(*tert*-butyl)pyrrolide dimer (equation 11). The solid-state structure of the compound, shown in Figure 14, shows an unusual binding mode for  $\text{Pyr}^*$  with high steric shielding (see *Steric*

Effect) of the central Zn–Cl–Zn moiety. The Pyr\* ligand and the chlorine atom bridge the zinc atoms that are found on the same side of the ligand. One zinc atom is bound to the N of the Pyr\* ligand, while the other is bound in a  $\eta^2$  fashion to the opposite C atoms.<sup>58</sup>

In the different examples presented above, the coordination at zinc suggests that both  $\sigma$ - (see  *$\sigma$ -Bond*) and  $\pi$ -type interactions (see  *$\pi$ -Bond*) contribute to the cyclopentadiene–zinc bonding.

## 2.4 Coordination of Diorganozinc Compounds (See *Coordination Theory*)

In its ground state (see *Ground State*), the zinc atom has the electronic configuration  $[\text{Ar}] 3d^{10}4s^2$  (see *Electronic Structure of Main-group Compounds*) and so, the low-lying 3d shell is completely filled. Therefore the coordination chemistry (see *Coordination Numbers & Geometries*) of zinc is mainly determined by electrostatic factors with no ligand field effects. In terms of simple valence theory (see *Valence Bond Theory*), the zinc atom in diorganozinc compounds is  $sp$ -hybridized (see *Hybridization*) with a linear geometry and two low-energy orbitals remain available for coordination with electron-donating ligands. Additionally, this capacity to form complexes is enhanced by the low electronegativity (see *Electronegativity*) of zinc ( $\chi_{\text{Zn}} = 1.7$ ), making it a rather electropositive element when bound to carbon ( $\chi_{\text{C}} = 2.5$ ).

If only one coordinate bond is formed between the diorganozinc and a ligand, the zinc atom becomes  $sp^2$ -hybridized (see *Hybridization*) with the typical trigonal planar geometry and it still has an unoccupied valence orbital (see *Valence Orbitals*). This case is quite rare and usually favored with sterically hindered ligands that can avoid the approach of a fourth ligand. When two-coordinate bonds are formed, the zinc atom becomes approximately  $sp^3$ -hybridized (see *Hybridization*) with the typical tetrahedral or pseudotetrahedral geometry. This is the most common situation, encountered in the majority of complexes with diorganozinc species. Despite five- and six-coordinated zinc atoms being common in inorganic zinc chemistry (see *Zinc: Inorganic & Coordination Chemistry*), this situation is rare for organozinc compounds. Finally, intramolecular (see *Intramolecular*) coordination may occur when the alkyl groups of  $\text{R}_2\text{Zn}$  include donor atoms (see *Donor Atom*) or insaturations.<sup>59</sup>

### 2.4.1 Coordination with Oxygen-containing Ligands

When diorganozinc compounds dissolve in ethereal solvents, they readily form complexes with either one or

two molecules of the solvent. Complexes with straight chain dialkyl ethers as  $\text{Me}_2\text{O}$  or  $\text{Et}_2\text{O}$ , have been known for a long time but they are generally not stable enough to be isolated.<sup>60</sup> Nevertheless, with cyclic ethers such as THF, and also with bifunctional ethers like 1,4-dioxane or 1,2-dimethoxyethane, the resulting complexes are more stable and some of them could be characterized. Several examples of ether complexes with diorganozinc compounds are presented in Table 3; all of them possess a tetracoordinated zinc center.<sup>61</sup>

The coordination of few diorganozinc species with crown ethers (see *Crown Ethers*) has been studied. The reaction of  $\text{Ph}_2\text{Zn}$ <sup>64</sup> or  $\text{Et}_2\text{Zn}$ <sup>65</sup> with 18-crown-6-ether leads to the formation of the corresponding rotoxane (Figure 15). The average Zn–C bond length found in the  $\text{Et}_2\text{Zn}$  rotoxane [1.957(5) Å] is almost identical with that found in gaseous  $\text{Et}_2\text{Zn}$  [1.950(2) Å], whereas it is somewhat longer in the  $\text{Ph}_2\text{Zn}$  rotoxane [1.984(3) Å]. The Zn–O distances are extremely long [average >2.8 Å] indicating only weak Zn–O bonding. Therefore these rotoxanes might be best regarded as clathrates (see *Clathrate*), having nearly linear  $\text{R}_2\text{Zn}$  encapsulated within the crown ether (see *Crown Ethers*) but only weakly bonded to its oxygens. The mechanism of formation of threaded  $\text{Ar}_2\text{Zn} \cdot (18\text{-crown-6})$  species has been studied.<sup>66</sup> The observations indicate that  $\text{R}_2\text{Zn}$  and 18-crown-6 rapidly form a 1:1 peripheral complex and more slowly form a rotoxane. The formation and dethreading of the rotoxane require free  $\text{R}_2\text{Zn}$ . Thus pure rotoxane is stable indefinitely in a benzene solution unless some  $\text{R}_2\text{Zn}$  compound is added.

A different coordination mode has been found with 1,3-xylyl 15-crown-4 and 1,3-xylyl 18-crown-5 ethers.<sup>67</sup> The crystal structure of three adducts with  $\text{Ph}_2\text{Zn}$  shows that bonding takes place only with two oxygens of the cryptand (see

**Table 3** Physical properties of ether complexes with diorganozinc compounds

|                                                               | M.P. (°C) | B.P. (°C) |

**Figure 15** Structure of rotoxane  $\text{R}_2\text{Zn} \cdot 18\text{-crown-6}$

*Cryptands & Cryptates*) (Figure 16), leading to a tetrahedrally surrounded zinc atom which remains outside the cavity of the crown ether (*see Crown Ethers*).

To date, the only five-coordinated Zn adduct structurally characterized is formed between  $\text{Ph}_2\text{Zn}$  and diglyme<sup>62</sup> (Figure 17) and has been shown to persist in solution.

Finally, an unusual planar-trigonal geometry of the zinc atom has been observed in the molecular structure of  $(i\text{-PrOSiMe}_2\text{CH}_2)_2\text{Zn}$ .<sup>68</sup> This situation results from intermolecular (*see Intermolecular*) coordination of one oxygen atom belonging to a neighboring molecule (Figure 18). Table 4 outlines important bond lengths and bond angles found in some adducts of dialkylzinc compounds with oxygen-containing ligands.

#### 2.4.2 Coordination with Nitrogen-containing Ligands

The coordination chemistry of diorganozinc compounds with nitrogen-containing ligands has been known for many

**Figure 16** Coordination of  $\text{Ph}_2\text{Zn}$  with 1,3-xylyl crown ethers. R = H, Br

**Figure 17** Structure of  $\text{Ph}_2\text{Zn}\cdot\text{diglyme}$

**Figure 18** Intermolecular coordination in the solid state of bis[(dimethylisopropoxysilyl)methyl]zinc

**Figure 19** Chelate complexes between dialkylzinc compounds and TMEDA

years, but until recently only little structural information was accessible. Zinc–nitrogen coordinate bonds are stronger than zinc–oxygen coordinate bonds because of the relatively soft character (*see Hard & Soft Acids and Bases*) of zinc (*b*-type) in diorganozinc compounds. But, even though tertiary amines form very stable complexes, primary and secondary amine-complexes are usually unstable as a result of the protonolysis of the zinc–carbon bonds by the nitrogen-bound hydrogen(s) (equation 12). When bidentate ligands (*see Bidentate Ligand*) such as TMEDA are used, chelate complexes (*see Chelate Effect*) are formed<sup>71</sup> (Figure 19). This property has been successfully used to synthesize and isolate heteroleptic (*see Heteroleptic Compound*) diorganozinc compounds ( $\text{RZnR}'$ ) which are otherwise unstable.<sup>72,73</sup> In fact, the occupation of the coordination sites at the zinc atom prevents dismutation to the homoleptic (*see Homoleptic Compound*) derivatives ( $\text{R}_2\text{Zn}$  and  $\text{R}'_2\text{Zn}$ ). It is also worth mentioning that the complex between  $\text{Me}_2\text{Zn}$  and the chelate ligand (*S,S*)-*NN'*-ethylenebis(1-phenylethylamine) [(*S,S*)-*ebpe*] is the sole example of a complex between a dialkylzinc compound and a secondary amine to be isolated

and characterized by X-ray crystallography.<sup>74</sup>

In the 1960s, Thiele<sup>54,75,76</sup> reported the preparation of complexes with both monodentate (e.g. triethylamine, pyridine) and bidentate ligands (*see Bidentate Ligand*) (e.g. 2,2-bipyridyl, 1,10-phenanthroline). While low-boiling liquid adducts were obtained with monodentate ligands, both in the 1:1 and 2:1 ligand to diorganozinc ratio, volatile solid adducts were obtained with bidentate ligands. As shown by cryoscopic molecular weight measurements in nonpolar solvents, extensive dissociation occurred for the 2:1 species giving equilibrium mixtures of the 1:1 adduct, the free amine and the 2:1 species. Eventually, on repeated distillation, these liquids of 2:1 stoichiometry reach a stable 1:1 stoichiometry. The adducts with N-heterocyclic ligands such as pyridine, 2,2'-bipyridine and 1,10-phenanthroline, are brightly colored owing to metal-to-ligand charge-transfer transitions.<sup>77</sup> A series of complexes between dialkylzinc compounds and bipyridine has been studied. The variation of the dissociation constants indicates that the metal-nitrogen bond strength increases with the size of the alkyl group; bigger alkyl groups provide more electron density, reducing the Lewis acidity (*see Lewis Acids & Bases*) of the metal but increasing back bonding (*see Back Bonding*) to the ligand.<sup>4</sup>

Recently there has been revived interest for adducts of dimethylzinc and diethylzinc with nitrogen-containing ligands owing to their useful application as precursors in metal organic chemical vapor deposition<sup>78</sup> (*see Metal–Organic Chemical Vapor Deposition*) (MOCVD) and in the purification of metal alkyls for subsequent use in MOCVD.<sup>79</sup> Less volatile adducts such as  $[R_2Zn\{(C_5H_4N)(CH_2)_3(C_5H_4N)\}]_n$  have been used for the production of electronic grade  $R_2Zn$  by mild thermal dissociation.<sup>80</sup>

A number of relevant structures have been published. Table 5 summarizes some of the important bond lengths and bond angles found in complexes between diorganozinc compounds and amines. As a result of amine coordination, the geometry around the zinc center changes from linear to distorted tetrahedral (*see Coordination Numbers & Geometries*).

It is noteworthy that the potentially tridentate triazine ligand coordinates only via one of its nitrogen atoms to form the  $[Me_2Zn(CH_2NMe)_3]_2$ .<sup>81</sup> In contrast, the reaction of  $Et_2Zn$  with 1,4-diazabicyclo[2,2,2]octane (DABCO) results in the formation of molecular chains in which the metal atom exhibits a distorted tetrahedral geometry through coordination to one nitrogen atom of two different DABCO molecules<sup>82</sup> (Figure 20).

The coordination of  $Me_2Zn$  with macrocyclic amines (*see Macrocyclic Ligands*) such as 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane ( $N_4$ -aza crown) and 1,4,7,10,13,16-hexamethyl-1,4,7,10,13,16-hexaazacyclooctadecane ( $N_6$ -aza crown) has been studied.<sup>85</sup> As shown by X-ray diffraction analysis, the structure of the complexes consists of molecular units with distorted tetrahedral coordination at zinc (Figure 21, Table 5). In  $(Me_2Zn)_2[N_4\text{-aza crown}]$ , the

$\text{Me}_2\text{Zn}$  forms two six-membered chelate rings, clearly favored over the more sterically strained five-membered configuration, whereas in  $(\text{Me}_2\text{Zn})_2[\text{N}_6\text{-aza crown}]$ , the  $\text{Me}_2\text{Zn}$  forms two five-membered chelate rings. While the  $\text{N}_4\text{-aza crown}$  adduct has the predictable  $\text{Me}_2\text{Zn}:\text{ligand}$  stoichiometry of 2:1, steric constraints (*see Steric Effect*) in the  $\text{N}_6\text{-aza crown}$  adduct limit the stoichiometry to 2:1. These adducts thermally dissociate at relatively low temperatures, making them suitable for  $\text{Me}_2\text{Zn}$  purification and its further use in MOCVD (*see Metal–Organic Chemical Vapor Deposition*).

The structures of some complexes with perfluoroalkylzinc derivatives have also been determined by X-ray diffraction. The first fully characterized compound of this type was the pyridine adduct  $[(\text{CF}_3)_2\text{Zn}(\text{C}_5\text{H}_5\text{N})_2]$ , which presents the typical four-coordinated zinc center with a distorted tetrahedral geometry<sup>86,87</sup> (Table 5). The tetramethyltetrazene ligand forms a four-membered chelate ring via a 1,3-coordination with  $(\text{C}_6\text{F}_5)_2\text{Zn}$ <sup>88</sup> (Figure 22).

#### 2.4.3 Coordination with other Ligands

The synthesis and characterization of  $\text{Et}_2\text{Zn}$  adducts with nucleophilic carbenes (*see Carbene Complexes*) have been described.<sup>89</sup> They are directly available and in good yields from a smooth reaction between  $\text{Et}_2\text{Zn}$  and stable carbenes (*see Carbene Complexes*) such as 1,3-dimesitylimidazol-2-ylidene or 1,3-di(1-adamantyl)imidazol-2-ylidene (equation 13). The solid-state structure of  $[\text{Et}_2\text{Zn}\{1,3\text{-di}(1\text{-adamantyl})\text{imidazol-2-ylidene}\}]$  shows a zinc atom in a rather unusual trigonal planar arrangement, certainly due to a steric

protection of the zinc center by the adamantyl substituents.

The recent preparation of  $[\text{Ph}_2\text{Zn}\{\text{S}(\text{CH}_2)_n\}_2]$  ( $n = 3, 4$ ) represent the first examples of complexes between a diorganozinc compound and a sulfur donor ligand.<sup>90</sup> The molecular structure of  $[\text{Ph}_2\text{Zn}\{\text{S}(\text{CH}_2)_4\}_2]$ , determined by X-ray crystallography, reveals a dimeric association with carbon-bridging groups (Figure 23).

#### 2.4.4 Intramolecular Coordination

Diorganozinc compounds containing potential coordinating substituents beyond the  $\alpha$  position generally exhibit intramolecular (*see Intramolecular*) coordinative interactions between the substituent groups and the central zinc atom.<sup>52</sup> This is the case for all the compounds containing carbon–carbon multiple bonds and those containing oxygen, nitrogen, sulfur, and phosphorus (Figure 24). In a study involving bis[3-(dimethylamino)propyl]zinc, both electron diffraction in gas phase and X-ray diffraction in solid state show a weak contact, around 0.23 nm, between the nitrogen and the zinc atom.<sup>91</sup> Analogous intramolecular coordination of the heterocyclic-*N* is found in the sterically hindered complex  $[(2\text{-C}_5\text{H}_4\text{N})(\text{Me}_3\text{Si})_2\text{C}]_2\text{Zn}$ <sup>92</sup> or with the amine-*N* in 2-[(dimethylamino)methyl]phenyl- and 2-(dimethylamino)benzyl derivatives.<sup>93,94</sup>

The monomeric zinc complex  $[\text{Zn}(2\text{-C}_6\text{H}_4\text{PPh}_2\text{NSiMe}_3)_2]$ , which was recently obtained by reaction of the *ortho*-metallated species  $[\text{Li}(2\text{-C}_6\text{H}_4\text{PPh}_2\text{NSiMe}_3)_2] \cdot \text{Et}_2\text{O}$  with  $\text{ZnCl}_2$  in THF, represents a good example of side-arm intramolecular coordination.<sup>95</sup> Its molecular structure determined by X-ray crystallography shows a tetrahedrally

Figure 24 Intramolecular adducts

Figure 25 Structure of  $[Zn(2-C_6H_4PPh_2NSiMe_3)_2]$ 

coordinated zinc atom with a Zn–C distance (2.008 Å) comparable to those found in diarylzinc compounds and a Zn–N distance (2.158 Å) typical for Zn–N dative bonds (Figure 25).

In compounds containing multiple carbon–carbon bonds, such as  $[CH_2=CH(CH_2)_3]_2Zn$  and  $[MeC\equiv C(CH_2)_3]_2Zn$ , interactions between the multiple bond and the zinc center are also proposed on the basis of NMR spectra ( $^1H$  and  $^{13}C$ ) and Raman spectroscopy.<sup>96,97</sup> An electron diffraction study of the linear di-3-butenylzinc and the molecular structure of  $(2,4-t-Bu_2C_5H_5)_2Zn$  determined by X-ray diffraction have been published.<sup>52,98</sup>

Interestingly, the intramolecular coordination of the carbon–carbon double bond in  $[CH_2=CH(CH_2)_4]_2Zn$  is thought to be responsible for the formation of di(cyclopentylmethyl)zinc in 90% yield when the compound is kept several days at 120 °C (equation 14).<sup>99</sup>

### 3 ORGANOZINC COMPOUNDS OF THE TYPE $RZnX$

#### 3.1 Organozinc Halides

##### 3.1.1 Preparation

The procedures used for the preparation of diorganozinc compounds must be modified in order to obtain organozinc

halide derivatives. The aim of these modifications is to avoid the Schlenk-type equilibrium which leads to diorganozinc derivatives (equations 1 and 2) although the positions of the equilibria are such that the  $R-Zn-X$  compounds are favored. In the last decade, this subject has been included in different reviews concerning the applications of polyfunctional organozinc compounds.<sup>8–10</sup>

**Direct Reaction of Zn with Alkyl Halides.** The direct insertion (*see Insertion*) reaction of Zn metal into alkyl halides – alkyl iodides being the ideal substrates – is a useful reaction to prepare simple or polyfunctional organozinc halide compounds (equation 1). With primary alkyl iodides, the reaction requires an excess of Zn dust (ca. 3 equiv), previously treated with few mol % of 1,2-dibromoethane and TMSCl, and a temperature of 40 °C in THF. In these conditions, secondary alkyl iodides react at room temperature and benzylic and allylic bromides at 0 °C. The insertion (*see Insertion*) into less activated C–X bonds may require more reactive forms of zinc (Riecke zinc), higher temperatures, or the use of polar (*see Polar Compounds*) solvent or cosolvent.

A novel and simple modification uses the catalysis with iodine in dimethylacetamide<sup>100</sup> (DMA) (equation 15). In these conditions, any form of metallic zinc can be used (dust, powder, granule, shot), a variety of functional groups is tolerated, and the use of less reactive alkyl chlorides is possible, although in this special case the reaction requires stoichiometric amounts of bromide salts. Electrochemical procedures, using a sacrificial zinc anode (*see Sacrificial Anode*), have been successfully employed to prepare organozinc halides from aryl bromides and chlorides in high yields, even those that are unreactive in the Riecke process.<sup>101,102</sup> Recently it was found that reducing agents can advantageously replace electricity and the group of Périchon developed a purely chemical reaction based on the activation of aryl bromides by low-valent cobalt species arising from the reduction of cobalt halide by zinc dust.<sup>103</sup> A possible catalytic cycle is shown in Scheme 5.

Numerous modifications of the direct zinc insertion procedure can be found in the literature. For example, simple dialkylzincs can be used as reagents instead of metallic Zn, but in this case the reaction is accelerated by catalytic quantities of zinc salts or transition metal (*see Transition Metals*) salts. Whereas the  $Cu^I$ -catalyzed iodine–zinc exchange reaction provides diorganozincs, the  $Pd^{II}$ ,  $Mn^{II}$  and  $Ni^{II}$  catalyzed iodine- or bromine–zinc exchange leads to organozinc halides.

**Lithium–Zinc Transmetallation.** The transmetallation reaction of organolithium reagents with zinc salts is a more

Scheme 5

straightforward approach to organozinc halide derivatives, but the high reactivity and instability of these very polar (*see Polar Compounds*) reagents limit the applicability of this reaction. However, alkenyl- and aryllitiums are known to be less reactive than their alkyl counterparts. Thus, at low temperature ( $-100\text{ }^{\circ}\text{C}$ ), they tolerate a range of functional groups and readily undergo transmetalation reaction with zinc halides, leading to the corresponding organozinc halides<sup>21,104</sup> (equation 16).

X = Br, I. FG = functional group.

(16)

**Other Preparations.** A less general procedure involves the reaction of diorganomercurials with zinc dust in the presence of zinc bromide.

Allyliczinc halides reagents have been prepared from sterically hindered homoallylic alcohols, using a novel fragmentation reaction of the corresponding zinc alkoxide<sup>105</sup> (Scheme 6). The interest of this reaction resides in the absence of the Wurtz homocoupling product, usually present in high proportion when the direct reaction of zinc with allylic halides is used.

An *in situ* (*see In Situ Reaction*) generation of zinc acetylides has been performed in very mild conditions by the combination of a terminal alkyne with  $\text{Zn}(\text{OTf})_2$  and a tertiary amine base<sup>106</sup> (equation 17). The zinc acetylides were

not isolated but they could be unequivocally identified by the large, characteristic shifts of the  $^{13}\text{C}$  NMR corresponding to the *sp*-hybridized (*see Hybridization*) carbons.

### 3.1.2 Structure of Organozinc Halides

As a result of the Schlenk-type equilibrium (equation 2), alkylzinc halide solutions are believed to contain some amounts of the corresponding dialkylzinc compound and zinc halide salt. The equilibrium usually lies on the left side in such a way that the alkylzinc halide compound is favored. Nevertheless, as already mentioned in Section 2, the equilibrium can be shifted to the right by distillation of the more volatile dialkylzinc derivative or by addition of complexing agents to remove the zinc dihalides from the solution.

Although organozinc halides have been extensively used in organic synthesis for many years, comparatively little information is available concerning their structure and coordination behavior. The crystalline ethylzinc iodide is a coordination polymer, with the iodine–zinc linkages giving rise to a layer structure as shown in the Figure 26. Each iodine atom forms one short (2.64 Å) and two long (2.91 Å) bonds to zinc.<sup>107</sup>

Ethylzinc chloride and ethylzinc bromide are tetrameric in benzene solutions and are believed to have the cubane-type structure<sup>108</sup> shown in Figure 27. In the  $\text{Zn}_4\text{X}_4$  core, the zinc-halogen coordination is relatively weak; consequently when these compounds dissolve in coordinating solvents or when

**Figure 26** Part of the ethylzinc iodide polymer in the solid state

Scheme 6

they are reacted with ligands like TMEDA or bipyridine, they exist as monomeric complexes.<sup>84</sup> The highly sterically demanding  $(\text{PhMe}_2\text{Si})_3\text{CZnCl}$  exist as a dimer in solid state, with tricoordinate zinc atoms and bridging chlorine atoms.<sup>109</sup> As shown in Figure 27, the solid-state structure of the complex consists of a planar arrangement of zinc and chlorine atoms forming a parallelogram.

The reaction between lithiated bidentate ligands (*see Bidentate Ligand*), such as lithium (dialkylaminoethyl)cyclopentadienide or  $[2\text{-C}_5\text{H}_4\text{N}(\text{Me})_2\text{Si}(\text{Me}_3\text{Si})_2\text{C}]\text{Li}$ , with zinc dihalide ( $\text{ZnX}_2$ ) also leads to dimeric derivatives containing bridging chlorine atoms but with tetracoordinate zinc centers as a result of intramolecular (*see Intramolecular*) coordination<sup>55,110</sup> (Figure 13 and 28 respectively). A cryoscopic study of  $\text{Et}_2\text{N}(\text{CH}_2)_3\text{ZnCl}$  in benzene solution has shown a related dimeric structure with bridging chlorines independent of the concentration<sup>111</sup> (Figure 28). Selected bond lengths and bond angles for dimeric alkylzinc halide compounds characterized by X-ray crystallography are reported in Table 6.

A number of monomeric adducts between alkylzinc halide compounds and chelating ligands (*see Chelating Ligands*) have been isolated and structurally characterized (Table 7). For example, the reaction between the TMEDA adduct of lithium-phenyl(trimethylsilyl)methanide and  $\text{ZnCl}_2$ <sup>63</sup> directly led to the formation of the TMEDA

**Figure 27** Structure of polymeric  $\text{EtZnX}$  ( $\text{X} = \text{Br}, \text{Cl}$ ) (a) and dimeric  $(\text{PhMe}_2\text{Si})_3\text{CZnCl}$  (b)

complex of phenyl(trimethylsilyl)methanidezinc chloride. Its molecular structure determined by X-ray diffraction crystallography, and that of  $\text{EtZnCl}$ -TMEDA, are presented in Figure 29.

Even if alkylzinc halides in the absence of chelating ligands (*see Chelating Ligands*) or coordinating solvents generally form dimeric or polymeric species with bridging halogen atoms, a different situation has been found with the Reformatsky reagents derived from the ethyl- and *tert*-butyl esters of bromoacetic acid.<sup>113</sup> In the crystalline state,  $(\text{Br}-\text{Zn}-\text{CH}_2\text{COO}^t\text{Bu})_2$  exists as a dimeric unit consisting of a nonplanar 8-membered  $(\text{ZnCCO})_2$  ring in which the THF coordination is preferred over the  $\text{Zn}-\text{Br}-\text{Zn}$  bridging (Figure 30). A rather short C–C bond length (1.41 Å)

**Figure 30** Structure of  $(t\text{BuOCOCH}_2\text{ZnBr})_2$

associated to a quite long carbonyl C–O bond distance (1.31 Å) suggest that the Reformatsky reagent exists neither as a strictly C-metalated species nor as a strictly O-metalated form, but rather as a combination of the two. Association measurements and NMR spectroscopy studies show that the reagents are dimeric in all but the most polar (see *Polar Compounds*) solvents like dimethylsulfoxide.

Among the alkylzinc halide compounds, iodomethylzinc iodide deserves a special attention owing to its important applications in organic synthesis. This highly reactive reagent can be stabilized by chelation to ethers or even more efficiently to bipyridine.<sup>114</sup> In the later case, the resulting adducts are stable enough to be stored several months in the freezer with almost no decomposition. The complexes of  $\text{ICH}_2\text{ZnI}$  with 18-crown-6 and benzo-18-crown-6 ethers have been prepared and structurally characterized by X-ray diffraction crystallography.<sup>115</sup> The two structures are very similar; they reveal a coordination of three oxygen atoms from the crown ether (see *Crown Ethers*) to the zinc atom (Figure 31). Interestingly, this is one of the few crown ether-derived complex in which the metal atom is not centrosymmetric. Selected bond lengths and bond angles for alkylzinc halides coordinated to oxygen-containing ligands are found in Table 8.

### 3.2 Alkylzinc Compounds Containing a Zinc–Oxygen Bond

There are two principal classes of alkylzinc compounds containing a zinc–oxygen bond, that is, those derived from aliphatic and aromatic alcohols (commonly called alkylzinc

**Figure 31** Structure of  $\text{ICH}_2\text{ZnI} \cdot 18\text{-crown-6}$  complex

alkoxides and aryloxides) and those derived from other oxygen-containing compounds like water, carboxylic acids, silanol, boronic acids, and so on. Recently,  $\text{Zn}^{\text{II}}$  alkoxide or phenoxide derivatives have attracted much interest for their ability to catalyze numerous reactions, such as enantioselective (see *Enantioselectivity*) alkylation of aldehydes, asymmetric epoxidation of  $\alpha,\beta$  unsaturated ketones, decarboxylation of carboxylic acids, copolymerization (see *Oligomerization & Polymerization by Homogeneous Catalysis*) of carbon dioxide with epoxides.

#### 3.2.1 Alkylzinc Alkoxides and Aryloxides

**Preparation.** The synthesis of alkylzinc alkoxides and aryloxides is achieved by an alkane elimination process in the simple reaction of a dialkylzinc compound,  $\text{R}_2\text{Zn}$ , with one equivalent of an alcohol,  $\text{R}'\text{OH}$  (equation 18). This reaction proceeds either in hydrocarbon solvents or neat solution, to give essentially quantitative yields of the desired products. The volatility of the  $\text{RH}$  side product helps to drive the equilibrium to the right. The formation of relatively strong Zn–O and C–H bonds, at the expense of breaking the O–H and a relatively weak Zn–C bond also guarantee favorable reaction energetics.

**Structure.** The presence of an oxygen atom directly bound to zinc increases both the electron deficiency of the zinc and the donor character of the oxygen atom. This condition will inevitably result in intermolecular (see *Intermolecular*) association increasing the coordinative saturation of zinc and leading to high thermal stability and low sensitivity towards oxygen and moisture. Organozinc alkoxides and aryloxides

**Table 8** Selected bond lengths and bond angles for some alkylzinc halide complexes with oxygen-containing ligands

| Compound                                                              | Zn–C(Å) | Zn–X(Å) | Zn–O(Å)        | C–Zn–X(°) | O–Zn–O(°) |

**Figure 32** Tetrameric MeZn-OMe (a), trimeric *t*-BuZnO-*t*-Bu (b) and dimeric Me<sub>3</sub>Si(Me<sub>2</sub>)CZn<sub>2</sub>,4,6-*t*-Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub> (c)

are usually colorless or light-yellow solids. Depending on the nature of the alkyl and alkoxide groups and on the degree of association, they can be either highly soluble or virtually insoluble in both apolar and polar organic solvents.

The coordination chemistry (*see Coordination Numbers & Geometries*) of organozinc alkoxides and aryloxides is very diverse but follow fairly well established patterns that can be rationalized mainly on the basis of steric considerations (*see Steric Effect*). As shown in Figure 32, the solid-state structure of methylzinc methoxide is tetrameric.<sup>118</sup> Although this tetrameric association with distorted cubic Zn<sub>4</sub>O<sub>4</sub> core is observed as a common feature, the degree of association decreases with increasing bulk of the alkyl and alkoxide groups, resulting in trimeric<sup>119</sup> or dimeric species,<sup>120</sup> for example, [*t*-BuZn-(O-*t*-Bu)]<sub>3</sub> and [(Me<sub>3</sub>SiCH<sub>2</sub>)(Me)<sub>2</sub>CZnO-2,4,6-*t*-Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub>]<sub>2</sub> (Figure 32). The structure of these complexes also depends on the presence of potentially intramolecular coordinating donor atoms in either the organic or the alkoxide group. Such donor atoms are often involved in intramolecular coordination and may give rise to a very complex coordination behavior.

A number of alkylzinc complexes derived from phenoxide ligands, containing one or two potentially coordinating NMe<sub>2</sub> groups, have been studied by cryoscopic molecular weight determination.<sup>121</sup> When the potentially chelating groups (*see Chelating Ligands*) are in positions that result in the formation of six-membered chelate rings upon intramolecular coordination, the complexes are dimers or dimer–monomer equilibria, and when the potential chelate ring size is decreased from six- to five-membered, trimeric aggregation is observed (Figure 33). The introduction of bulky substituents in a potential five-membered chelate ring leads to further dissociation, and dimer formation becomes favorable. The dimer formation can also be favored when a strongly electron-withdrawing group is bound to the oxygen, leading to a weaker zinc–oxygen coordinate bond. Therefore, when ethylzinc phenoxide is a tetramer the related ethylzinc pentafluorophenoxide is a dimer.<sup>119</sup>

Multinuclear aggregates of alkylzinc derivatives have been prepared and structurally characterized by the reaction between tris(3,5-dialkyl-2-hydroxyphenyl)methanes with dimethyl- or diethylzinc.<sup>122</sup> Depending on both the steric

**Figure 33** Intramolecular coordination in alkylzinc alkoxides

requirements (*see Steric Effect*) of the dialkylzinc reagent/trisphenol precursors and on the solvent used, hexa-, penta-, tetra-, and trinuclear aggregates are isolated. The reactions of polyalcoholic compounds (diphenol and triphenol derivatives) have also been studied, they lead to a variety of products depending on the conditions used.<sup>123,124</sup>

When the zinc atom is coordinatively unsaturated or when the oxygen atoms bound to zinc have a low electron density rising from mesomeric or inductive effects, the compounds can easily form complexes with coordinative reagents like pyridine and TMEDA.

In some cases, alkylzinc compounds containing oxygen are subject to redistribution equilibria.<sup>125,126</sup> This is shown in solution by the presence of different species. For example, compounds of general formula R<sub>6</sub>Zn<sub>7</sub>(OMe)<sub>8</sub> can be isolated from solutions of [RZn(OMe)]<sub>4</sub> (R = Et, Me). The structure of these aggregates, as shown in Figure 34, consists of two Zn<sub>4</sub>O<sub>4</sub> cubic

**Figure 34** Structure of (RO)<sub>8</sub>Zn<sub>7</sub>R'<sub>6</sub>

cores sharing a zinc atom. Interestingly, it has been found that the related compound  $(\text{ICH}_2)_6\text{Zn}_7(\text{MeO})_8$  is cleanly formed when a solution of ethylzinc methoxide and diiodomethane is photochemically (*see Photochemistry*) irradiated.<sup>127</sup>

In the last years, a large number of alkylzinc alkoxide or aryloxy derivatives have been prepared and structurally characterized. They have gained interest for their valuable catalytic activity for various reactions including enantioselective alkylation of aldehydes, asymmetric epoxidation of  $\alpha,\beta$ -unsaturated ketones, and the copolymerization of carbon dioxide with epoxides (Section 6). Some selected averaged bond lengths found in organozinc compounds containing a zinc–oxygen bond are summarized in Table 9.

### 3.2.2 Other Organozinc Compounds Containing Oxygen

The dialkylzinc compounds are extremely moisture sensitive and even react explosively with bulk water. Nevertheless, cryoscopic studies carried out on the controlled hydrolysis of diethylzinc show the formation of organozinc hydroxide  $\text{EtZnOH}$  as intermediate.<sup>130,131</sup> This intermediate, which is thought to have the dimeric structure  $(\text{EtZnOH})_2$ , is very unstable and reacts further to give polymers of the form  $\text{Et}(\text{ZnO})_n$  (equation 19). Some of these products exhibit a good catalytic activity for the polymerization of lactones and cyclic ethers.

The stabilization approach with bulky ligands allowed the isolation of the stable alkylzinc hydroxide dimer, that is,  $[\{\text{Zn}(\mu\text{-OH})\text{C}(\text{SiMe}_2\text{Ph})_3\}_2]$  (Figure 35), obtained by reaction of  $(\text{Me}_2\text{PhSi})_3\text{CZnCl}$  with  $\text{NaOH}$ .<sup>132</sup> The hydroxy group is characterized by a sharp  $\nu(\text{OH})$  IR absorption at  $3680\text{ cm}^{-1}$ .

Zinc siloxides derived from  $\text{Si-OH}$  species have received considerable attention in recent years, since they can be used as precursors for metal silicates and mixed-metal oxide systems as well as for models for heterogeneous silica-supported catalytic systems and complex zeolite systems.

**Table 9** Average bond lengths for some structurally characterized organozinc compounds containing a zinc–oxygen bond

| Compound                                                                                  | Zn–C<br>(Å) | Zn–O<br>(Å) | E–O/[E]<br>(Å) |

**Figure 35** Structure of dimeric  $[\{\text{Zn}(\mu\text{-OH})\text{C}(\text{SiMe}_2\text{Ph})_3\}_2]$

A polyhedral zinc siloxane compound, which was obtained in the reaction between dimethylzinc and trimethylsilanol, has been reported in 1965.<sup>133</sup> More recently, di-, tri-, and tetranuclear compounds of this kind have been prepared; the nature of the product being dependent on the molar ratio of the monosilanol to the alkylzinc compounds and on the steric demand (*see Steric Effect*) of the substituents at both the oxygen and zinc atoms.<sup>134,135</sup> The structures for the di- and tetranuclear species are similar to those found with alkoxide derivatives (Figure 32). In contrast, the trinuclear alkylzinc siloxides show a specific type of association, that is, two four-membered rings sharing a zinc atom (Figure 36). Recently, larger aggregates which remain soluble in organic solvents, have been prepared using the silanetriol  $\text{RSi}(\text{OH})_3$  [ $\text{R} = 2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3\text{N}(\text{SiMe}_3)$ ]. Its reaction with an excess of  $\text{Me}_2\text{Zn}$  in THF/hexane at room temperature led to the neutral compound  $[\text{Zn}_4(\text{THF})_4(\text{MeZn})_4(\text{O}_3\text{SiR})_4]$ ,<sup>136</sup> while the ionic zinc siloxane  $(\text{LZnLiO}_3\text{SiR})_4$  was obtained when  $\text{MeLi}$  and  $N,N,N',N'$ -tetramethyl-1,4-phenylenediamine ( $\text{L}$ ) were present in the reaction mixture.<sup>137</sup> The molecular structure of the neutral aggregate exhibits a  $\text{Zn}_8\text{Si}_4\text{O}_{12}$  core in which the zinc atoms are in a variety of geometries and coordination environments (Figure 36).

Recently, some interest in the chemistry of metal diorganoboryloxides  $[\text{M}(\text{OBR}_2)]$  has emerged from their potential catalytic activity. Some alkylzinc diorganoboryloxides  $[\text{RZn}(\text{OBR}_2)]$  have been prepared with the expectation that the  $p\pi\text{-}p\pi$  interaction between boron and oxygen may reduce  $\pi$ -donor properties of the latter, and consequently decrease the tendency for autoassociation to afford a coordinatively unsaturated boron atom.<sup>138</sup> Unfortunately, the diverse results obtained so far show no significant difference between diorganoboryloxides and typical alkoxides in their reactivity with dialkylzinc. Typical  $\text{Zn}_4\text{O}_4$  heterocubane cores were obtained when  $(9\text{-BBN})_2\text{O}$  ( $9\text{-BBN} = 9\text{-Borabicyclo-}3,3,1\text{-non-}9\text{-yl}$ ) or  $(\text{Et}_2\text{B})_2\text{O}$  was treated with  $\text{Et}_2\text{Zn}$  in toluene at room temperature (Figure 32). A less classic discrete dimer  $[(\text{Mes}_2\text{BO})\text{ZnEt}]_2$ , comparable to the dimeric alkoxides  $[(2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3\text{O})\text{-ZnCH}_2\text{SiMe}_3]_2$  and  $[(2,4,6\text{-}t\text{-Bu}_3\text{C}_6\text{H}_2\text{O})\text{-ZnCH}_2\text{SiMe}_3]_2$  (Figure 32), has been obtained in the reaction of dimesitylborynic acid ( $\text{Mes}_2\text{BOH}$ ) with diethylzinc in toluene at  $0^\circ\text{C}$ .<sup>139</sup>

The preparation and reactions of alkylzinc enolates have been studied. The main methods for their synthesis are metal exchange between lithium enolates and zinc chloride,<sup>140</sup> deprotonations of carbonyl compounds with

**Figure 36** Structures of the trinuclear aggregate  $[\text{Zn}(\text{R}'\text{Zn})_2(\text{OSiR}''_3)_4]$  (a), the core of the neutral  $[\text{Zn}_4(\text{THF})_4(\text{MeZn})_4(\text{O}_3\text{SiR}'')_4]$  (b) and the ionic  $(\text{LZnLiO}_3\text{SiR})_4$  (c) ( $\text{R} = 2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3\text{N}(\text{SiMe}_3)$ )

basic alkylzinc amides,<sup>141</sup> reduction of  $\alpha$ -bromo carbonyl compounds<sup>142</sup> (Reformatsky reaction) and addition reactions of dialkylzincs to  $\alpha,\beta$ -unsaturated carbonyl and heterocarbonyl compounds<sup>143–145</sup> (Scheme 7). Spectroscopic studies of the resulting alkylzinc ketone enolates suggest the presence of oxygen- rather than carbon-bound metal species. Oxygen-metalated compounds have also been found in *N*-protected  $\alpha$ -amino-substituted zinc ester enolates.<sup>146</sup> In this case, the zinc atom is fixed via *N,O*-chelation, and intramolecular aggregates of various composition are formed. The same *N,O*-chelation occurs in ethyl zinc derivatives of  $\beta$ -carbonyl sulfoximines with formation of dimeric aggregates through dative  $\text{Zn}-\text{O}$  interactions in the case of  $\beta$ -ketosulfoximine, and through  $\text{Zn}-\text{C}$  interactions in the case of  $\beta$ -amidosulfoximine.<sup>147</sup>

Organozinc carboxylates formally derived from carboxylic acids are prepared *via* protonolysis of diorganozinc compounds by carboxylic acids (equation 20). Although dimeric carbamate complexes of the general formula  $[\text{RM}(\text{E}_2\text{CNR}'_2)]_2$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ,  $\text{R} = \text{Me}$  or  $\text{Et}$ ,  $\text{R}' = \text{alkyl}$ ,  $\text{M} = \text{Zn}$  or  $\text{Cd}$ ) are readily formed by reaction of  $\text{CE}_2$

with  $\text{RM}(\text{NR}'_2)$ <sup>148,149</sup> (equation 21), insertion (*see Insertion*) of  $\text{CO}_2$  into methylzinc diethylamide leads to unusual species such as the tetramers  $[\text{Me}_2\text{Zn}_4(\text{O}_2\text{CNEt}_2)_6]$  and  $[\text{Me}_4\text{Zn}_4(\text{O}_2\text{CNEt}_2)_4]$ <sup>150,151</sup> (Figure 37). Diorganozinc compounds are typically unreactive towards insertion of carbon dioxide into the zinc–carbon bond with one exception, that is, the specific activation of diethylzinc by *N*-methylimidazole.<sup>152</sup>

$\text{E} = \text{O}, \text{S}, \text{Se}$

### 3.3 Alkylzinc Compounds Containing a Zinc–Sulfur or Zinc–Selenium Bond

Heteroleptic (*see Heteroleptic Compound*) alkylzinc thiolate and selenolate compounds present two major interests; they can be used as models for metalloenzyme activity<sup>153</sup> and as precursors for the formation of binary metal sulfides and selenides.<sup>154</sup> Furthermore, these compounds tend to

**Scheme 7**

**Figure 37** Structures of  $[\text{Me}_4\text{Zn}_4(\text{O}_2\text{CNEt}_2)_4]$  and  $[\text{Me}_2\text{Zn}_4(\text{O}_2\text{CNEt}_2)_6]$

oligomerize leading to a variety of inorganic rings (*see Inorganic Ring Systems*) or larger aggregates with interesting optical and electronic properties.

### 3.3.1 Preparation

The title compounds are usually obtained in a straightforward manner and in almost quantitative yields by alkane elimination process between a dialkylzinc compound  $\text{ZnR}_2$  and the desired thiol  $\text{R}'\text{SH}$  or selenol  $\text{R}'\text{SeH}$  species<sup>155,156</sup> (equation 18). This reaction works equally well in hydrocarbon solvent or neat solution. If thiocyanogen  $(\text{SCN})_2$  is used as the reagent, then alkylzinc thiocyanate derivatives  $(\text{RZnSCN})$  are obtained.<sup>157</sup>

A different strategy, involving chlorotrimethylsilane elimination from the reaction of a  $\text{Zn}^{\text{II}}$  or  $\text{Cu}^{\text{I}}$  halide with (trimethylsilyl)arenethiolates  $\text{RSSiMe}_3$ , has been described for the preparation of zinc- and copper arenethiolates<sup>158</sup> (equation 22).

Although insertion (*see Insertion*) of elemental sulfur into the zinc-carbon bond of dialkylzinc has not been studied extensively, it has been described in the special case of diethylzinc for the preparation of  $\text{EtZn}(\text{SEt})$ <sup>159</sup> (equation 23).

Mixed alkylzinc dithio- or diselenocarbamates of general formula  $\text{RZnE}_2\text{CNEt}_2$  ( $\text{R} = \text{Me}_3\text{SiCH}_2, \text{Me}_3\text{C}$ ;  $\text{E} = \text{S}, \text{Se}$ ) are prepared by two different ways, namely, ligand redistribution between the corresponding dialkylzinc ( $\text{R}_2\text{Zn}$ ) and bis(dithio- or bis(diseleno- carbamato)zinc compounds<sup>160</sup> (equation 24), and insertion of  $\text{CE}_2$  into the zinc-nitrogen bond of a mixed alkylzinc amide  $\text{RZnNR}'_2$  which was first reported by Noltes (Section 3.2.2 equation 21).<sup>161</sup>

### 3.3.2 Structure

Alkylzinc thiolate compounds are insoluble or poorly soluble in hydrocarbon solvents, indicating their tendency to form aggregates. Indeed, all the compounds that have been structurally characterized obey the empirical formula  $(\text{RZnSR}')_n$  with values of  $n$  varying from 2 to 10. As shown in Figure 38, these species reveal a remarkable structural chemistry.<sup>158</sup> The dimeric complex  $(\text{Me}_3\text{SiCH}_2\text{ZnSCPh}_3)_2$  possesses a planar  $\text{Zn}_2\text{S}_2$  array with trigonal planar zinc atoms and trigonal pyramidal sulfur centers. The core of the trimers  $[\text{Me}_3\text{SiCH}_2\text{ZnS-}i\text{-Pr}_3\text{C}_6\text{H}_5]_3$  and  $[\text{Me}_3\text{SiCH}_2\text{ZnS-}t\text{-Bu}_3\text{C}_6\text{H}_5]_3$  consists of an almost planar six-membered  $\text{Zn}_3\text{S}_3$  ring, suggesting that the six nonbonded electron pairs of the sulfur atoms tend to delocalize (*see Delocalized Bonding*). More complicated arrays are found in the solid-state structure of the pentamer  $[\text{MeZn}(\text{S-}t\text{-Bu})]_5$ <sup>162</sup> and the octamer  $[\text{MeZn}(\text{S-}i\text{-Pr})]_8$ .<sup>163</sup> Interestingly, the octameric aggregation of the last compound is not retained in benzene solution where hexamers are observed. Finally, a wurtzite-like structure has been found for the decamer  $[\text{EtZn}(\text{SEt})]_{10}$ .<sup>159</sup> The pentamer  $[\text{MeZn}(\text{S-}t\text{-Bu})]_5$  readily reacts with nitrogenous bases like pyridine and 1,3,5-trimethylhexahydro-1,3,5-triazine to form stable adducts of the dimeric species,<sup>164</sup> which, in contrast to the parent oligomers, present a good solubility in organic solvents. A selection of average bond lengths in organozinc compounds containing a zinc-sulfur bond can be found in Table 10.

Recently, some mononuclear alkylzinc complexes containing a zinc-sulfur bond could be prepared and structurally

**Figure 38** Structure of the  $[\text{RZn}(\text{SR}')_n]$  cores that have been structurally characterized

**Table 10** Average bond lengths for some structurally characterized organozinc compounds containing a zinc–sulfur bond

| Compound                                                               | Zn–C<br>(Å) | Zn–S<br>(Å) | C–S<br>(Å) |

characterized using the monoanionic bis- and tris (mercaptoimidazolyl)hydroborate ligands<sup>165,166</sup> (Figure 39). Their preparation follows the metathesis reaction between the corresponding thallium complexes and dimethylzinc (equation 25). The complexes with tridentate ligands show a classic pseudotetrahedral coordination geometry around the zinc atom, but an interesting feature is found in the solid-state structure of the bis(mercaptoimidazolyl)hydroborate derivative, that is, the presence of a ‘boat like’ eight-membered ring that allows for intramolecular (*see Intramolecular*) interaction between the zinc atom and one BH ligand ( $d\text{ Zn} \cdots \text{B} = 2.88 \text{ Å}$ ;  $d\text{ Zn} \cdots \text{H} = 1.77 \text{ Å}$ ). The compounds are strictly monomeric in the solid state but undergo redistribution reactions in solution to give the homoleptic (*see Homoleptic Compound*) species L<sub>2</sub>Zn. In contrast, a monomeric solid-state structure which subsists in solution has been found for [MeZn(PATH)] (PATH = 2-methyl-1-[methyl-(2-pyridin-2-ylethyl)amino]propane-2-thiolate) (Figure 40). This complex is a valuable synthetic precursor to other complexes that are good models for the catalytic site of metalloenzymes.<sup>153</sup>

So far, the only alkylzinc selenolate compound to be structurally characterized is the trimeric [Me<sub>3</sub>SiCH<sub>2</sub>ZnSe-2,4,6-*t*-Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub>]<sub>3</sub>. In contrast with the parent compound

[Me<sub>3</sub>SiCH<sub>2</sub>ZnS-2,4,6-*t*-Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub>]<sub>3</sub>, the central Zn<sub>3</sub>Se<sub>3</sub> possesses a twist structure with more pyramidal geometries at selenium.<sup>167</sup> However, it is worth mentioning that various diselenolato- and ditelluroloatozinc compounds have been prepared and their adducts with nitrogenous bases such as TMEDA and pyridine could be structurally characterized.<sup>168–170</sup> Furthermore, the reaction of sterically hindered chalcogenolato compounds [Zn(EAr\*)<sub>2</sub>]<sub>2</sub> (E = S, Se; Ar\* = 2, 4, 6-*t*-Bu<sub>3</sub>C<sub>6</sub>H<sub>2</sub>) with excess tert-butyliisocyanide gave the first examples of well-characterized isocyanide complexes of zinc Zn(EAr\*)<sub>2</sub>(CN-*t*-Bu)<sub>2</sub>.<sup>171</sup>

Alkylzinc thio- and selenocarbamate derivatives are commonly air-sensitive white crystalline solids, with the thiocarbamate derivatives being more soluble in organic solvents than the selenocarbamate derivatives. They have been found to be dimers of general formula [RZnE<sub>2</sub>CNR']<sub>2</sub>, in which each carbamate chelates one metal atom and bridges to the next one (Figure 41). The zinc atoms are four-coordinate with a distorted tetrahedral geometry.

Two new bonding modes have been found for the monothiocarbamate ligand in the novel tetrameric complex [Et<sub>4</sub>Zn<sub>4</sub>(OSCNET<sub>2</sub>)<sub>2</sub>(NET<sub>2</sub>)<sub>2</sub>], which was prepared by reaction of EtZnNET<sub>2</sub> with carbonyl sulfide.<sup>172</sup> The cage compound contains two six-membered Zn<sub>2</sub>CNOS cycles and both the oxygen and sulfur are binucleating (Figure 42).

### 3.4 Organozinc Compounds Containing a Zinc–Nitrogen Bond

In recent years, the interest for the preparation of alkylzinc amides has been motivated by their potential application as catalyst for polymerization of propylene oxide, and also as precursors for the MOCVD (*see Metal–Organic Chemical Vapor Deposition*) process.

#### 3.4.1 Preparation

Even though zincation of secondary amines was already studied by Frankland in 1856 and 1867, it is only in the past few decades that some efforts were made to isolate and characterize the products. Numerous compounds of the type RZnNR'<sub>2</sub> or Zn(NR'<sub>2</sub>)<sub>2</sub> can now be prepared using two principal procedures, namely the zincation of amines with simple dialkylzinc compounds<sup>173–175</sup> (equation 26) and the metathesis reaction of alkali metal amides with anhydrous zinc dihalide (equation 27).

The first step of the zincation route is the formation of an adduct between the amine and the dialkylzinc compound. Such a complex can rarely be isolated since one of the Zn–C bonds readily suffers protonolysis. Mechanistic studies of the

**Figure 39** Zinc alkyls stabilized by (mercaptoimidazolyl)hydroborato ligands

**Figure 40** Structure of MeZn(PATH)

**Figure 41** Dimeric organozinc thio- and selenocarbamates. E = S, Se

protonolysis step in the reaction of various dialkylzinc compounds with cyclohexylamine and *p*-toluidine, have shown an  $S_E1$  mechanism.<sup>176</sup> The reaction can easily be stopped at the mono substitution product because the remaining C–Zn bond is far less reactive than in the parent dialkylzinc compounds.

A very fast reaction occurs between dialkylzinc compounds and the more acidic amide and thioamide derivatives of the

**Figure 42** Structure of  $\text{Et}_4\text{Zn}_4(\text{OSCNEt}_2)_2(\text{NEt}_2)_2$

type  $\text{HNPhCXR}'$  ( $\text{X} = \text{O}$  or  $\text{S}$ ), leading to  $\text{RZnNPhCXR}'$  complexes. An alternative route for the preparation of such compounds is the insertion reaction (*see Insertion*) of iso- and isothio-cyanates into the Zn–O and Zn–N bond of monosubstituted organozinc derivatives<sup>161</sup> (equations 28 and 29).

Some heteroleptic (*see Heteroleptic Compound*) alkylzinc amides have been prepared by addition reaction of dialkylzinc compounds ( $\text{ZnR}_2$ ) on 1,4-di-*tert*-butyl-1,4-diaza-1,3-butadiene ( $t\text{-BuN}=\text{CHCH}=\text{N-}t\text{-Bu}$ ). Extensive studies<sup>177,178</sup>

**Scheme 8**

**Figure 43** Structure of  $(R'_2NZnR)_n$

have shown that the addition is regioselective (*see Regioselectivity*) to the *N*-alkylated product  $RZn(t\text{-Bu}N(R)CH=CHN\text{-}t\text{-Bu})$  when *R* is a primary alkyl group, and to the *C*-alkylated product  $RZn(t\text{-Bu}NCH(R)CH=N\text{-}t\text{-Bu})$  when *R* is a tertiary or benzylic alkyl group (Scheme 8). The reaction probably follows a radical mechanism subsequent to the initial formation of the coordination complex  $R_2Zn\cdot(t\text{-Bu}N=CHCH=N\text{-}t\text{-Bu})$ .

Very recently, the preparation of zinc  $\beta$ -diiminate derivatives became the subject of interest due to their catalytic activity in the copolymerization of  $CO_2$  with epoxides.<sup>179–181</sup> They can be prepared in high yields by direct reaction of the corresponding  $\beta$ -diimines with dialkylzinc compounds or by treatment of the  $\beta$ -diimine-lithium salts with zinc halide followed by an alkylation reaction (Scheme 9).

### 3.4.2 Structure

Nitrogen has only one nonbonding electron pair (*see Lone Pair*); consequently, alkylzinc amide compounds generally do not form the typical cubic structure found with alkylzinc alkoxide derivatives. Various alkylzinc amides derived from secondary amines and few derived from primary amines have been structurally characterized. Depending on the steric demand (*see Steric Effect*) of the substituents at both the zinc and the nitrogen atom different degrees of association are observed in solid state. For example, the highly sterically hindered  $(Me_3Si)_3CZn\text{-}N(H)Si\text{-}i\text{-}Pr_3$  and  $(Me_3Si)_3CZn\text{-}N(SiMe_3)_2$  exist as monomers<sup>182</sup> with an almost

linear C–Zn–N center for the latter. Dimers with a central planar four-membered ring are formed with less bulky primary amines such as 2,4,6-trimethylaniline, 2,6-diisopropylaniline or triisopropylsilylamine<sup>174</sup> (Figure 43). This coordination mode is also typical for alkylzinc dialkylamide compounds. Trimers with a chair-shaped  $Zn_3N_3$  ring are obtained in the reaction of dimethyl- or diethylzinc with *tert*-butylamine and naphtylamine.<sup>175</sup> The unusual structure observed in the dimeric compound  $\{(\eta^1\text{-Cp})Zn\}_2(\mu\text{-Cp})\{\mu\text{-}N(SiMe_3)_2\}$ , readily prepared by combining  $Cp_2Zn$  and  $Zn[N(SiMe_3)_2]_2$  in hot benzene, has already been mentioned in Section 2.3.3<sup>54</sup> (Figure 12). Table 11 lists some selected bond lengths found in organozinc compounds containing a Zn–N bond.

Finally, as a result of intra- or intermolecular (*see Intermolecular*) coordination, a large variety of association modes is observed when the amine residue contains electron-donating atoms in appropriate position. Two extremely rare examples of monomeric three-coordinate zinc complexes have been obtained by the reaction of  $R_2Zn$  (*R* = Me, Et) with *N*-(2-diphenylphosphinophenyl)-2,6-diisopropylaniline in  $Et_2O$  at  $-35^\circ C$ .<sup>183</sup> As shown in Figure 44, the molecular

**Scheme 9**

structure of the ethyl derivative, determined by X-ray analysis, indicates a trigonal planar geometry at zinc (sum of the bond angles = 359.81°) and typical distances for the three different bonds Zn–C (1.956 Å), Zn–P (2.445 Å), and Zn–N (1.911 Å). The compounds were found to be highly sensitive towards hydrolysis, but thermally very stable under inert atmosphere as they do not show decomposition after three days at 100 °C in toluene.

The reaction of *N,N,N'*-trimethylethylene- or propylene-diamine (HNMe(CH<sub>2</sub>)<sub>n</sub>NMe<sub>2</sub>; *n* = 2 or 3) with dimethyl- or diethylzinc gives dimeric molecular units of general formula [RZnNMe(CH<sub>2</sub>)<sub>n</sub>NMe<sub>2</sub>]<sub>2</sub> (Figure 45). A central four-membered ring is formed with bridging nitrogen atoms and two five- or six-membered side rings are respectively produced by intramolecular (see *Intramolecular*) coordination of the amino group.<sup>184</sup>

Bis- and tris(pyrazolyl)borato ligands have been widely used to stabilize a variety of alkylmetal complexes among which several alkylzinc derivatives.<sup>185</sup> Stable monomeric three-coordinate alkylzinc complexes, {η<sup>2</sup>-H<sub>2</sub>B(3-*t*-Bupz)<sub>2</sub>}ZnR, could be prepared by reaction of R<sub>2</sub>Zn with the thallium derivative Tl{η<sup>2</sup>-H<sub>2</sub>B(3-*t*-Bupz)<sub>2</sub>} (equation 30). In these complexes, both the B–H and the Zn–C bonds are potential reactive sites; while ketones and aldehydes react at the former, protic reagents react at the subsequent.<sup>186</sup> The tris(pyrazolyl)hydroborato ligand allowed the formation of monomeric four-coordinate zinc alkyl derivatives.<sup>187</sup> A comparison with analogous magnesium (see *Beryllium & Magnesium: Organometallic Chemistry*) complexes has shown that the Mg–C bond in these systems is more reactive than the related Zn–C bond, especially with respect to CO<sub>2</sub> insertion (see *Insertion*).

Although the cubic structure with a Zn<sub>4</sub>N<sub>4</sub> core is not as common as with alkoxy-zinc derivatives, it was recurrently found in tetrameric organozinc phosphoraneiminato complexes [RZn(NPR'<sub>3</sub>)<sub>4</sub>]. Several compounds with different R and R' groups (R' = Me, Et; R = Me, *n*-Bu, C≡CR'') were prepared in good yields by the reaction of [BrZn(NPR'<sub>3</sub>)<sub>4</sub>] with the corresponding organolithium reagent in hexane<sup>188,189</sup>

**Figure 45** Intramolecular coordination in [RZnNMe(CH<sub>2</sub>)<sub>n</sub>NMe<sub>2</sub>]<sub>2</sub> (*n* = 2, 3)

(equation 31). All the complexes that have been characterized by X-ray crystallography present a heterocubane Zn<sub>4</sub>N<sub>4</sub> structure – only slightly distorted from the cube – where the zinc atoms are linked via μ<sup>3</sup>-N bridges of the phosphoraneiminato groups. In the Zn<sub>4</sub>N<sub>4</sub> frame, all the bond angles are close to 90° and the Zn–N bond distances have an average value of 2.07 Å (Figure 46).

### 3.5 Alkylzinc Compounds Containing a Zinc–Phosphorus or Zinc–Arsenic Bond

#### 3.5.1 Preparation

Some interest in group 12 phosphide and arsenide complexes has come from their possible applications as precursors for II/V semiconductors (see *Semiconductors*). They can be prepared by two different ways, namely, by metallation reaction of phosphines and arsines with diorganozinc compounds (equation 32), and by transmetallation reaction between organozinc halides and lithium salt of the corresponding phosphines and arsines (equation 33).

**Figure 46** Structure of organozinc phosphoraneiminato complexes [RZn(NPR'<sub>3</sub>)<sub>4</sub>]

**Figure 47** Structure of  $(RZnER')_n$  ( $E = P, As$ ) and  $[(Me_3Si)_3CZn]_2PSi-i-Pr_3$

### 3.5.2 Structure

So far only few compounds of this family have been structurally characterized. The nonbonding electron pair present on the group 15 atom leads to intermolecular (*see Intermolecular*) associations similar to those observed in organozinc amides. The degree of association is controlled by the steric demand of the substituents at the zinc atom. For example, in solid state the general compound  $RZn[E(SiMe_3)_2]$  ( $E = P$  or  $As$ ) can form trimers<sup>190,191</sup> with a central cyclic  $Zn_3E_3$  core in a twist-boat conformation ( $E = P$ ,  $R = Me, Et, n\text{-Butyl}$ ;  $E = As$ ,  $R = Me, Et$ ) or dimers<sup>192,193</sup> with a central planar  $Zn_2E_2$  ring ( $E = P$ ,  $R = CH_2SiMe_3$ ) (Figure 47). An intermediate position is found with  $i\text{-PrZnP}(SiMe_3)_2$  which shows in solution a temperature-dependent equilibrium of dimeric and trimeric species, and gives a 1:1 mixture of these two oligomers in crystalline state.<sup>194</sup> So far, the only compound found to be monomeric both in crystalline state and in solution, is the binuclear bis[tris(trimethylsilyl)methylzinc]triisopropylsilylphosphandiide  $\{[(Me_3Si)_3CZn]_2PSi-i-Pr_3\}$  obtain in the reaction of tris(trimethylsilyl)methylzinc chloride with lithium triisopropylsilylphosphanide (equation 34). The crystalline structure of this compound shows a very short zinc–phosphorus bond of 2.23 Å, owing to the low-coordination state of the phosphorus and zinc atoms.<sup>195</sup>

A series of compounds with general formula  $[RMAs(t\text{-Bu})_2]_n$  ( $R = Me, t\text{-Bu}$ ;  $M = Zn, Cd, Hg$ ) has been studied and it was found that their stability decreases in the order  $Zn > Cd \gg Hg$ . Table 12 summarizes some representative average bond distances and bond angles found in organozinc compounds containing a phosphorus– or arsenic–zinc bond.

### 3.6 Alkylzinc Compounds Containing a Zinc-metal Bond

A number of compounds having a direct zinc transition metal bond are known for long time, that is, zinc-bis(transition metal) such as  $Zn[Co(CO_4)]_2$ <sup>196</sup> and transition metal zinc halides such as  $(CO)_4Fe(ZnCl)_2$ .<sup>197</sup> However, organozinc-transition metal compounds  $RZn-TM$  are comparatively more recent. They can be prepared by hydrocarbon elimination between a diorganozinc derivative and a transition metal hydride<sup>198</sup> (*see Hydrides*) (equation 35), but dialkyl- and diarylzinc compounds usually fail to react or react very slowly. Furthermore, when they do react they give unstable products that show a very strong tendency to disproportionate and cannot be isolated<sup>199</sup> (equation 36).

**Table 12** Average bond lengths and bond angles for some structurally characterized organozinc compounds containing a zinc–phosphorus or zinc–arsenic bond

| Compound                            | E  | Zn–C(Å) | Zn–E(Å) | Zn–E–Zn(°) | E–Zn–E(°) |
|-------------------------------------|----|---------|---------|------------|-----------|
| $[(Me_3Si)_3CZn]_2PSi-i-Pr_3$       | P  | 1.97    | 2.23    | 105.1      | –         |
| $[i\text{-PrZnP}(SiMe_3)_2]_2$      |    | 2.00    | 2.41    | 89.1       | 90.9      |

| $[i\text{-PrZnP}(SiMe_3)_2]_3$      |    | 1.99    | 2.41    | 115.8      | 111.7     |
| $[EtZnP(C_6H_{11})_2]_3 \cdot THF$  |    | 2.00    | 2.40    | 118.6      | 108.2     |
| $[MeZnP(SiMe_3)_2]_3$               |    | 1.97    | 2.23    | 121.9      | 111.2     |
| $[n\text{-BuZnP}(SiMe_3)_2]_3$      |    | 2.03    | 2.39    | 122.7      | 111.9     |
| $[(Me_3Si)_3CZn]_2AsSi-i-Pr_3$      | As | 1.97    | 2.32    |            |           |
| $[t\text{BuZnAs}(t\text{-Bu})_2]_2$ |    | 1.99    | 2.51    | 92.5       | 87.5      |
| $[MeZnAs(SiMe_3)_2]_3$              |    | 1.96    | 2.46    | 123.8      | 109.3     |
| $[EtZnAs(SiMe_3)_2]_3$              |    | 1.98    | 2.48    | 125.4      | 109.1     |

Data taken from The CSD System<sup>128</sup> using ConQuest.<sup>129</sup>

**Figure 48** Structure  $\text{Cp}_2\text{TMH}_{3-n}(\text{ZnCp})_n$  ( $n = 1, 2, 3$ )

However, it has been shown that  $\text{Cp}_2\text{Zn}$  is more reactive with transition metal hydrides (*see Hydrides*) and leads to more stable compounds. A number of complexes with different transition metals have been isolated by this route; these include derivatives of nickel (e.g.  $\text{Cp}_6\text{Ni}_2\text{Zn}_4$ ),<sup>200</sup> manganese (e.g.  $\text{CpZnMn}(\text{CO})_5$ ),<sup>201</sup> rhodium (e.g.  $[(\text{dipp})\text{Rh}]_2(\mu\text{-H})_2(\mu\text{-ZnCp})_2$ ),<sup>202</sup> tantalum (e.g.  $\text{Cp}'_2\text{TaH}_{3-n}(\text{ZnCp})_n$ ,  $n = 1, 2, 3$ )<sup>203</sup> and niobium  $\text{Cp}_2\text{NbH}_{3-n}(\text{ZnCp})_n$ , ( $n = 1, 2$ ).<sup>204</sup> The greater reactivity of  $\text{Cp}_2\text{Zn}$  can be appreciated in its stoichiometric reaction with  $\text{Cp}_2\text{NbH}_3$ , which gives the disubstituted  $\text{Cp}_2\text{NbH}(\text{ZnCp})_2$  as the only product. The isolation of  $\text{Cp}_2\text{NbH}_2\text{ZnCp}$  requires the use of a coordinating solvent like THF to decrease the reactivity of  $\text{Cp}_2\text{Zn}$ . This last compound and the related  $\text{Cp}'_2\text{TaH}(\text{ZnCp})_2$  ( $\text{Cp}' = \text{methylcyclopentadienyl}$ ) have been structurally characterized, they resemble the parent molecule  $\text{Cp}_2\text{NbH}_3$  and  $\text{Cp}'_2\text{TaH}_3$  with one or two hydrogens replaced by one or two  $\text{ZnCp}$  groups, respectively (Figure 48).

Stable organozinc transition metal compounds can also be obtained when the alkyl group bound to zinc is a chelating ligand (*see Chelating Ligands*) such as the (dimethylamino)propyl group  $[\text{Me}_2\text{N}(\text{CH}_2)_3]$  or the 2-[(dimethylamino)methyl]phenyl group  $(2\text{-C}_6\text{H}_4\text{CH}_2\text{NMe}_2)$  (Figure 49). A number of complexes with different transition metals have been isolated; that is, manganese, cobalt, molybdenum, and tungsten.<sup>59</sup> The crystal structure of  $\text{Me}_2\text{N}(\text{CH}_2)_3\text{ZnW}(\text{Cp})(\text{CO})_3$ , determined by X-ray crystallography, shows a tricoordinate zinc atom with a zinc–tungsten bond distance of 2.685 Å.

**Figure 49** Intramolecular coordination in organozinc transition metal compounds

Organozinc compounds containing a zinc main-group metal bond are extremely rare. With the exception of compounds containing zinc–zinc and zinc–nickel bonds such as the clusters (*see Cluster*)  $\text{Cp}'_6\text{Ni}_2\text{Zn}_4$  ( $\text{Cp}'_6 = \text{Cp}_6$ ,<sup>200</sup>  $\text{Cp}_2^*\text{Cp}_4$ ,<sup>205</sup>  $(\text{Me}_3\text{SiC}_5\text{H}_3)_6$ ),<sup>206</sup> only few zincate derivatives (*see Section 4.1*) containing weak contacts between zinc and different metals such as Ba,<sup>207</sup> Li,<sup>208</sup> or Na have been structurally characterized (Figure 50).

It is also worth mentioning here that two compounds containing a Zn–Sn coordinate bond have been reported. The first of these is the sole example of a dialkyltin<sup>II</sup> species (*see Tin: Organometallic Chemistry*) stabilized by coordination to zinc-β-diketonate. It was obtained by reaction of bis[3-dimethylamino)propyl]zinc with bis(dibenzoylmethanato)tin (equation 37) and its molecular structure shows a Zn–Sn bond length of 2.634 Å.<sup>209</sup> The second compound is

**Figure 50** Organozinc compounds containing Zn main-group metal bond

the heterodimetallic complex  $[\text{MeSi}\{\text{SiMe}_2\text{N}(\text{Tol})\}_3\text{Sn}]_2\text{Zn}$  (Tol = *p*-toluyl), which was recently prepared together with the Cd and Hg derivatives, by reaction of  $[\text{MeSi}\{\text{SiMe}_2\text{N}(\text{p-Tol})\}_3\text{SnLi}(\text{OEt}_2)]$  with the corresponding  $\text{MCl}_2$  (M = Zn, Cd, Hg).<sup>210</sup> As shown in Figure 51, its molecular structure is unsymmetrical with only one stannate unit bound to zinc ( $d(\text{Zn-Sn}) = 2.578 \text{ \AA}$ ).

**Figure 51** Structure  $[\text{MeSi}\{\text{SiMe}_2\text{N}(\text{Tol})\}_3\text{Sn}]_2\text{Zn}$

## 4 ALKYLZINC ANIONS AND CATIONS

### 4.1 Alkylzinc anions (*See Anion*)

The alkylzinc anions, defined as ate complexes (*see Ate Complexes*), are heterodimetallic systems which can be divided in two different classes, namely, the trialkylzincates of general formula  $\text{M}^+\text{R}_3\text{Zn}^-$  and the tetraalkylzincates of general formula  $\text{M}^{2+}\text{R}_4\text{Zn}^{2-}$ . The first zincate derivatives, that is,  $\text{NaZnEt}_3$  and  $\text{KZnEt}_3$ , were prepared by Wanklyn in 1858 from the reaction of metallic sodium or potassium with diethylzinc<sup>211</sup> (equation 38). In spite of this early discovery, many of the efforts to study this class of compounds are

very recent. Today these heterodimetallic compounds are of great interest for inorganic and organic chemists because they show a unique reactivity and selectivity, different from those of either parent single-metal species. For example, they are known to achieve 1,4-conjugate addition to  $\alpha,\beta$ -unsaturated ketones,<sup>212</sup> to metalate aromatic halide or vinyl halides,<sup>213–215</sup> and to reduce various carbonyl compounds.<sup>216–218</sup>

#### 4.1.1 Preparation

Homoleptic (*see Homoleptic Compound*) triorganylzincates are readily prepared via the route originally used by Wanklyn, that is, the reaction of a metal with a dialkylzinc compound (equation 38). This reaction presents the advantage to avoid the incorporation of halide or pseudohalide (*see Pseudohalide*) in the products. When alkali metals (*see Alkali Metals: Organometallic Chemistry*) are used without solvent or in hydrocarbon solvent, the homoleptic  $\text{MZnR}_3$  species ( $\text{R} = \text{CH}_2\text{CMe}_3, \text{CH}_2\text{SiMe}_3$ ; M = Na, K) are obtained in good yield.<sup>219</sup> In contrast, the reaction in benzene solution produces the heteroleptic (*see Heteroleptic Compound*)  $\text{MZnPhR}_2$  resulting from the metallation of benzene<sup>220</sup> (equation 39).

Early studies of the reaction between diorganozinc compounds and alkaline earth metals (*see Alkaline Earth Metals: Organometallic Chemistry*) (Ca, Sr, Ba) were reported to give complexes with general formula  $\text{R}_2\text{M} \cdot \text{R}_2\text{Zn}$ .<sup>221</sup> Subsequent investigations of these complexes in solution using NMR, cryoscopy and UV techniques, have shown the existence of a complex equilibrium (Scheme 10) and also suggested a tetrahedral structure for the  $\text{ZnR}_4^{2-}$  ion.<sup>222</sup> While ionic species are favored in donor solvents, the free alkyl compounds and the contact ion pair  $\text{M}^{2+}\text{ZnR}_4^{2-}$  are favored in nonpolar (*see Polar Compounds*) solvents. Recently, barium and strontium bis{tris[(trimethylsilyl)methyl]zincates} have been prepared by this route.<sup>207</sup>

A different approach was used to prepare the magnesium derivative  $[\text{Mg}^{2+}(\text{THF})_6][(\text{PhCH}_2)_3\text{Zn}^-]_2$ , that is the addition of  $(\text{PhCH}_2)_2\text{Mg}$  to a THF solution of  $(\text{PhCH}_2)_2\text{Zn}$  in a 1:2 molar ratio (equation 40). It is interesting to note that the 1:1 molar ratio reaction produces the same compound with an equimolar amount of  $(\text{PhCH}_2)_2\text{Mg}$  that remains in solution.<sup>223</sup>

Homo- and heteroleptic (*see Heteroleptic Compound*) triorganozincates can also be prepared by reacting an

M = Alkaline earth metal, I = Free alkyl compounds, II = ate complex, III = contact ion pair, IV = solvated contact ion pair, V = free ions.

Scheme 10

organometallic reagent RM (M = Li, Na; R = alkyl, dialkylamide) with a diorganozinc compound  $\text{ZnR}'_2$  ( $\text{R}'$  = alkyl, dialkylamide) (equation 41). When the substituents are bulky, then potentially intramolecular coordinating groups (2- $\text{C}_6\text{H}_4\text{CH}_2\text{NMe}_2$ ) or the presence of a strong coordinating agent (TMEDA or crown ethers) appear necessary to isolate the trialkylzincate and prevent its dissociation into dialkylzinc and the organometallic reagent.<sup>224–226</sup> On the other hand, it was shown that addition of TMEDA to a solution of the zincate  $[(\text{THF})_6\text{Mg}][\text{Zn}(\text{CH}_2\text{Ph})_3]$  leads to its decomposition in the corresponding dialkylzinc and dialkylmagnesium (*see Beryllium & Magnesium: Organometallic Chemistry*) species.<sup>227</sup> Dialkyl(hydro)zincates ( $\text{MZnHR}_2$ ; M = Li, Na) have been obtained in situ (*see In Situ Reaction*) when lithium hydride (*see Hydrides*) LiH or sodium hydride NaH was reacted with a diorganozinc compound in a 1:1 molar ratio.<sup>216</sup>

Trialkylzincate compounds exhibit an  $sp^2$  hybridized (*see Hybridization*) zinc atom having 16 electrons in his outer shell; consequently, an empty valence orbital (*see Valence Orbitals*) remains available at the zinc atom for coordination of a fourth ligand to reach the 18-electron state (*see Eighteen Electron Compounds*). Thus, tetraalkylzincates ( $\text{M}_2^{2+}\text{R}_4\text{Zn}^{2-}$ ) are usually obtained directly when organometallic reagents ( $\text{MR}$ ; M = Li, Na, MgX) are reacted with dialkylzinc ( $\text{R}_2\text{Zn}$ ) compounds in a 2:1 molar ratio (equation 42), as well as in direct reaction of four equivalents of an organometallic reagent with zinc dihalides ( $\text{ZnX}_2$ ) (equation 43).<sup>228</sup> The first reaction allows the synthesis of heteroleptic tetraalkylorganozincates of general formula  $\text{M}_2^{2+}(\text{ZnR}_n\text{R}'_{4-n})^{2-}$  ( $n = 1$  to  $3$ ; R and  $\text{R}'$  = alkyl,  $\text{R}' \neq \text{R}$ ;  $\text{M}_2^{2+} = 2\text{Li}^+$ ,  $2\text{Na}^+$ ,  $\text{Mg}^{2+}$ ) by conveniently choosing the diorganozinc and organometallic species.

It is interesting to note that the readily available dilithium teramethylzincate was found to react with

trimethylsilyl cyanide ( $\text{Me}_3\text{SiCN}$ ) or trimethylsilylisothiocyanate ( $\text{Me}_3\text{SiSCN}$ ) to give the corresponding modified zincates  $\text{Me}_3\text{Zn}(\text{CN})\text{Li}_2$  and  $\text{Me}_3\text{Zn}(\text{SCN})\text{Li}_2$ <sup>229</sup> (equation 44).

Finally, zincate complexes of general formula  $\text{M}_n\text{Zn}_m\text{R}_{2m+n}$  react with  $\text{LiAlH}_4$  or  $\text{NaAlH}_4$  in ethereal solvents to give complex metal hydrides of zinc with composition  $\text{M}_n\text{Zn}_m\text{H}_{2m+n}$ <sup>230,231</sup> (M = Li, Na, K;  $n = 1$  to  $3$ ;  $m = 1$  or  $2$ ).

#### 4.1.2 Structure

Zincate complexes are colorless, air- and moisture-sensitive solids; indeed the low-molecular species are pyrophoric on contact with air and react explosively with water. However, they are usually stable at room temperature when stored under a nitrogen atmosphere.

On the basis of conductivity studies, it was shown that  $\text{NaZnEt}_3$  possesses a salt-like character,  $\text{Na}^+[\text{Et}_3\text{Zn}]^-$ . The X-ray structure determinations of higher molecular weight compounds  $\text{MZnR}_3$  (R =  $\text{CH}_2\text{Ph}$ , M = Mg; R =  $\text{CH}_2\text{SiMe}_3$ , M = K; R =  $\text{CH}_2$ -*t*-Bu, M = Na, K; R =  $\text{C}\equiv\text{CPh}$ , M = Na) revealed that the metal cation is separated from the zinc center of the counterion.<sup>219,220,223,232</sup> All the trialkylzincates cited before have in common a  $\text{ZnC}_3$  core in which the zinc atom is three-coordinate with an almost trigonal planar geometry (Figure 52).

A rather different situation was found in the solid-state structure of the heavier metal group 2 (*see Alkaline Earth Metals: Organometallic Chemistry*) complexes<sup>225,233</sup>  $[\text{M} \cdot (\text{THF})_n][\text{Zn}[(\text{CH}_2\text{SiMe}_3)_3]_2]$  (M = Sr,  $n = 2$ ; M = Ba,  $n = 4$ ). As shown in Figure 52, the trialkylzincate anions coordinate the metal cation like bidentate ligands (*see Bidentate Ligand*), via M–C–Zn three-center, two-electron bonds (*see Three-center Bond*), forming two four-membered  $\text{MC}_2\text{Zn}$  rings. Under application of ultrasound (*see Sonication*) in heptane, the barium derivative further reacts with additional barium metal to form a dimeric alkylidibariumtris(zincate) with a tetraanionic tris(zincate) ligand and a unique  $\text{Ba}_4\text{Zn}_2\text{C}_6$  core shown in Figure 53.

When the trialkylzincate contains suitably placed donor atoms, then intramolecular (*see Intramolecular*) coordination occurs. For example, the molecular structure of the complex

**Figure 52** Structure of some triorganozincate compounds

**Figure 53** Structure of the  $\text{Ba}_4\text{Zn}_2\text{C}_6$  in the dimeric alkylbarium-tris-zincate

$(2\text{-Me}_2\text{NCH}_2\text{C}_6\text{H}_4)_3\text{ZnLi}\cdot\text{THF}$  exhibits a four-coordinated zinc center with a distorted tetrahedral geometry, resulting from intramolecular coordination of an amino group.<sup>224</sup>

Comparatively few tetraalkylzincates have been structurally characterized. The crystal structure of  $\text{Me}_4\text{ZnLi}_2$  and  $\text{Me}_4\text{ZnK}_2$ , determined from X-ray powder diffraction studies, shows isolated  $[\text{Me}_4\text{Zn}]^{2-}$  units with a four-coordinate zinc center in a tetrahedral arrangement.<sup>234</sup> A series of metallacyclopentane compounds of the type  $[\text{LiL}_x]_2\text{Zn}[(\text{CHR})_4]_2$  ( $\text{R} = \text{H, Me}$ ;  $\text{L} = \text{TMEDA, THF}$ ;  $x = 1, 2$ ) have been prepared by treating  $\text{ZnCl}_2$  with the corresponding dilithium compounds  $\text{Li}(\text{CHR})_4\text{Li}$  in diethyl ether.<sup>208</sup> These compounds were found to be thermally very stable. As shown in Figure 54, the structure of  $[\text{Li}(\text{TMEDA})]_2\text{Zn}[(\text{CH}_2)_4]_2$  determined by X-ray crystallography, contains a central  $\text{ZnC}_4$  core with distorted tetrahedral geometry, which is connected to each of the two  $\text{Li}\cdot\text{TMEDA}$  rests via two bridging carbon atoms. It is

worth mentioning that the average distance  $\text{Zn-Li}$  ( $2.42 \text{ \AA}$ ) in this complex is comparable with the sum of their covalence radii ( $2.48 \text{ \AA}$ ). A similar structure has been found for the related  $[\text{Li}(\text{TMEDA})]_2\text{Zn}[(\text{CH}_2\text{SiMe}_2)_2]_2$  containing silicon atoms in the metallacyclopentane rings.<sup>235</sup>

Even if the solid-state structures known so far exhibit separated ions, the nature of the different species in solution is not yet certain. The  $^1\text{H}$  and  $^7\text{Li}$  NMR studies of methyllithium mixed with dimethylzinc (and dimethylmagnesium) in ether solutions have shown that complex species such as  $\text{Li}_2\text{Zn}(\text{CH}_3)_4$  and  $\text{Li}_3\text{Zn}(\text{CH}_3)_5$  are formed, and no 1:1 complex was observed.<sup>236</sup> Furthermore, other studies (conductivity, cryoscopy, NMR and UV spectroscopy) of ethyllithium solutions in diethylzinc and  $\text{MZnEt}_4$  solutions ( $\text{M} = \text{Ca, Ba, Sr}$ ) have shown the existence of complicated exchange equilibria between various species.

Finally, mixing toluene solutions of potassium *tert*-butoxide (*t*-BuOK) and diethylzinc results in the formation of the zincate  $[\text{Et}_2\text{Zn}(\text{O-}t\text{-Bu})]^- \text{K}^+$  (equation 45). An X-ray diffraction study of the compound reveals a dimeric structure,  $(2\text{K}^+) [\text{Et}_2\text{Zn}(\mu\text{-O-}t\text{-Bu})_2\text{ZnEt}_2]^{2-}$ , containing a four-membered  $\text{Zn}_2\text{O}_4$  ring<sup>237</sup> (Figure 55). This  $\text{Zn}_4\text{O}_4$  core is somewhat similar to that found for the neutral alkylzinc alkoxide  $[\text{EtZn}(\text{O-}2,4,6\text{-}t\text{-Bu}_3\text{-C}_6\text{H}_2)]_2$ , but with longer zinc-carbon bonds ( $d(\text{Zn-C})_{\text{neutral complex}} = 1.99$  and  $1.95 \text{ \AA}$ ,  $d(\text{Zn-C})_{\text{zincate complex}} = 2.07 \text{ \AA}$ ).

**Figure 54** Structure of  $[\text{Li}(\text{TMEDA})]_2\text{Zn}[(\text{CH}_2)_4]_2$  and  $[\text{Li}(\text{TMEDA})]_2\text{Zn}[(\text{CH}_2\text{SiMe}_2)_2]_2$

## 4.2 Alkylzinc Cations (See Cation)

### 4.2.1 Preparation

In contrast to organomagnesium (see *Beryllium & Magnesium: Organometallic Chemistry*) compounds, dialkylzinc derivatives do not disproportionate in coordinated zincate anions and organozinc cations under addition of cryptand (see *Cryptands & Cryptates*) or crown ether (see *Crown Ethers*). However, it was shown by NMR spectroscopy that both organozinc anion and cation are formed in benzene solution when equimolar amounts of diethylzinc, diphenylzinc and a cryptand (see *Cryptands & Cryptates*)  $\text{N}_4$ -aza crown ( $\text{N}_4$ -aza crown = 1,4,8,11-teramethyl-1,4,8,11-terazacyclotetradecane) were mixed<sup>238</sup> (equation 46). Furthermore, if triethylaluminum (a more effective  $\text{R}^-$  acceptor than  $\text{R}_2\text{Zn}$ ) was used instead of diphenyl zinc, then the complex  $[\text{EtZn}(\text{C})]^+ (\text{Et}_4\text{Al})^-$  ( $\text{C}$  = crown ether,  $\text{N}_4$ -aza crown) separated as a dense liquid phase (equation 47). Some recent studies have extended this reaction to organozinc halide and alkoxide derivatives, and also verified that the formation of ionic species is favored by nitrogen-containing macrocycles<sup>239–241</sup> (see *Macrocyclic Ligands*). A series of ethylzinc cationic complexes has been prepared by protonolysis of diethylzinc with acidic tertiary ammonium salts of  $\text{N}$ -alkylated 1,3,5-triazacyclohexanes ( $\text{R}_3\text{TAC}$ ) ( $\text{R}$  = Me, Bz, *i*-Pr, 4-fluorobenzyl). The products were found to have the general formula  $[(\text{R}_3\text{TAC})\text{Zn}(\text{Et})]\text{X}$  ( $\text{X}$  =  $\text{ClO}_4^-$ ,  $\text{BF}_4^-$ ,  $[\text{B}(\text{C}_6\text{F}_5)_4]^-$ ,  $\text{PF}_6^-$ ) and to be sensitive to protic reagents.<sup>242,243</sup>

Actually, the presence of crown ether (see *Crown Ethers*) is not necessary to prepare a cationic zinc species. It was found that the reaction between diorganozinc compounds  $\text{R}_2\text{Zn}$  ( $\text{R}$  = Me, Et, *t*-Bu) and  $[\text{H}(\text{OEt}_2)_2]^+ [\text{B}(\text{C}_6\text{F}_5)_4]^-$  in ether, led via alkane elimination to the salts  $[\text{RZn}(\text{OEt}_2)_3]^+ [\text{B}(\text{C}_6\text{F}_5)_4]^-$  in quantitative yields<sup>244</sup> (equation 48). The compounds were

isolated as colorless crystalline solids that are soluble in ether and dichloromethane.

### 4.2.2 Structure

The structure of the derivative  $[\text{EtZn}(\text{OEt}_2)_3]^+ [\text{B}(\text{C}_6\text{F}_5)_4]^-$  could be determined by X-ray crystallography<sup>244</sup> (Figure 56). The zinc atom is tetracoordinated with a slightly distorted tetrahedral geometry, and the zinc–carbon bond length of 1.964 Å is comparable with that observed in the methylzinc alkoxide species  $[\text{MeZn}(\text{O-}t\text{-Bu})]_4$  (1.955 Å).

A similar zinc–carbon bond length (1.93 Å) is found in the solid-state structure of the compound  $[(\text{Bz}_3\text{TAC})\text{Zn}(\text{Et})](\text{PF}_6)$ , in which the ethylzinc cation coordinates to three nitrogen atoms of the 1,3,5-triazacyclohexane ligand<sup>242</sup> (Figure 56). It is worth noting that the benzyl substituents occupy two different positions, and that the two short Zn–F distances (2.85 Å) indicate anion–cation contacts. These observations confirm the previous NMR spectroscopy studies in solution of the related series  $[(\text{R}_3\text{TAC})\text{Zn}(\text{Et})]\text{X}$ <sup>243</sup> ( $\text{R}$  = Me, Bz, *i*Pr, 4-fluorobenzyl;  $\text{X}$  =  $\text{ClO}_4^-$ ,  $\text{BF}_4^-$ ,  $[\text{B}(\text{C}_6\text{F}_5)_4]^-$ ).

## 5 GEMINATE ORGANODIMETALLIC SPECIES CONTAINING ZINC

The synthesis and reactivity of geminate organodimetallic compounds is a useful approach for the building of complex architectural molecules by combining multiple reactions in a single operation. These reagents, which possess two nucleophilic (see *Nucleophile*) sites on a single carbon atom, are valuable tools for organic chemists since they can form two C–C bonds in a one-pot reaction. The synthesis and reactivity of geminate organodimetallic derivatives have been recently reviewed.<sup>245,246</sup>

Figure 56 Structure of  $[\text{EtZn}(\text{OEt}_2)_3]^+$  and  $[\text{EtZn}(\text{Bz}_3\text{TAC})]^+$  ( $\text{PF}_6$ ) $^-$  cations

Scheme 11

### 5.1 Synthesis

Whereas a stoichiometric reaction of Zn/Cu couple with  $\text{CH}_2\text{I}_2$  leads to the well-known Simmons–Smith reagent ( $\text{ICH}_2\text{ZnI}$ ) (Section 6.6), the same reaction in presence of a large excess of zinc leads to an organo-*gem*-dizincio alkane (Scheme 11). The Zn/Cu couple can be efficiently replaced by a mixture of zinc dust and cuprous chloride, a mixture of zinc and  $\text{Me}_3\text{Al}$ , or a Zn/Pb couple. For example, the methylenating reagent ( $\text{XZnCH}_2\text{ZnCH}_2\text{ZnX} \cdot \text{THF}$ ), also known as the Nysted reagent, can be obtained by reaction of  $\text{CH}_2\text{X}_2$  ( $\text{X} = \text{Br}, \text{I}$ ) with Zn/Pb couple in THF (equation 49). It has been shown that the catalytic effect of Hg in the formation of geminal dizincio alkanes follows the mechanism presented in Scheme 12. It is worth mentioning here that Charette and co-workers reported in 2002 the first evidence for the formation of a geminate dizinc carbenoid upon mixing iodoform ( $\text{CHI}_3$ ) with diethylzinc ( $\text{Et}_2\text{Zn}$ ) or ethylzinc iodide ( $\text{EtZnI}$ ) at  $0^\circ\text{C}$ . The novel compound was found very efficient to undergo cyclopropanation reactions with olefins (Section 6.7).

Scheme 12

The allylmetalation reaction, reported by Gaudemar, is an elegant alternative route for the synthesis of *gem*-dimetallic compounds. The addition of allylzinc bromide on substituted vinyl Grignard reagents gives the organo-*gem*-dimetallic derivative in moderate yields (equation 50). Even if the exact mechanism of the reaction remains uncertain, three hypotheses deserve consideration: a suprafacial addition of the allylic zinc bromide to the vinyl metal with further dimerization, especially when  $\text{MX}_n = \text{Li}$  (path A); an anti-allylzincation of the vinyl metal (path B); formation of a mixed vinyl–allyl zinc species which undergoes a rearrangement similar to the

Scheme 13

Claisen rearrangement where zinc would act as the oxygen (path C) (Scheme 13). It has been found that the diastereoselectivity of allylmetalation is highly dependent on the temperature and on the nature of the solvent. Changing the solvent from THF to Et<sub>2</sub>O considerably improves the diastereoselectivity since the poorer Lewis basicity (*see Lewis Acids & Bases*) of Et<sub>2</sub>O accelerates the reaction and consequently allows lower temperature conditions. The different diastereomers can be independently obtained only by changing the stereochemistry of the starting vinyl Grignard reagent (Scheme 14).

The related addition reaction of allylzinc bromide to alkynyl zinc reagents in refluxing THF leads to a mixture of vinylic 1,1-organo-*gem*-dimetallic species and *gem*-trimetallic species, which respectively result from single and double additions (equation 51). The presence of a Lewis basic (*see Lewis Acids & Bases*) group suitably placed for intramolecular (*see Intramolecular*) chelation, and bearing a secondary substituent, avoids the formation of double addition products and allows the reaction to take place in mild conditions (equation 52).

Scheme 14

1,1-Boro zincioalkane and 1,1-boro zincioalkene can be prepared by a different route, that is, the reaction of  $\alpha$ -haloboronic esters with zinc dust in *N,N*-dimethylacetamide (DMA). The zinc insertion (*see Insertion*) into  $\alpha$ -haloalkenylboronic esters is not stereospecific, so a pure *Z* reagent will be converted to an *E/Z* mixture of the corresponding alkenylzinc iodide (equation 53).

Other mixed *gem*-dimetallic compounds containing zinc and either zirconium, aluminum, or titanium have been successfully prepared from alkynylzinc halide compounds via hydrozirconation by H(Cl)ZrCp<sub>2</sub> (the Schwartz's reagent) or carbometalation by a combination of Me<sub>3</sub>Al/Cp<sub>2</sub>TiCl<sub>2</sub> (Scheme 15).

## 5.2 Structure

Compared with organo-*gem*-dilithio and dimagnesium compounds, the corresponding organo-*gem*-dizincio derivatives are relatively more stable and less reactive. However, they are usually prepared in situ (*see In Situ Reaction*) and directly

Scheme 15

reacted with electrophiles (*see Electrophile*); so, despite their great synthetic value, very little is known about their structure. The first structurally characterized organo-*gem*-dizincio species, namely, the  $[\text{Zn}\{\text{C}(\text{SiMe}_3)(2\text{-pyridyl})\}]_4$  tetrameric cage, has been reported only a few years ago.<sup>84</sup> This novel compound was obtained in low yield (20%) by reacting a distibine polymer  $[\{(2\text{-pyridyl})(\text{SiMe}_3)\text{C}\}\text{SbCl}]_\infty$  with  $\text{Et}_2\text{Zn}$  (equation 54). As shown in Figure 57, the compound contains a tetrameric array of  $\{(2\text{-pyridyl})(\text{Me}_3\text{Si})\text{C}\}\text{Zn}$  in which each ligand bridges two zinc atoms via the *gem*-C centers and bridges to a third zinc atom through the pyridyl nitrogen atom. The three-coordinate metal centers present a distorted trigonal planar geometry with a C–Zn distance of 2.032 Å. The *gem*-C centers are distorted from the tetrahedral environment with a Zn–C–Zn angle of 82.2(2)°.

The only other geminal dizincated alkane reported so far is the dimeric alkylidibarium triszincate,  $(4\text{Ba}^{2+}) \cdot \{[(\text{Me}_3\text{SiCH}_2)_2\text{ZnCH}(\text{SiMe}_3)]_2\}^{4-}$ , the synthesis and structure of which have already been mentioned in Section 4.1.2.<sup>233</sup> So as to make it clear, Figure 58 shows only the structure

Figure 57 Schematic structure of  $[\text{Zn}\{\text{C}(\text{SiMe}_3)(2\text{-pyridyl})\}]_4$ Figure 58 Structure of the tetraanionic tris(zincate) ligand of  $\{[(\text{Me}_3\text{SiCH}_2)_2\text{ZnCH}(\text{SiMe}_3)]_2\text{ZnCH}(\text{SiMe}_3)\}_2^{4-} \cdot 4\text{Ba}^{2+}$ 

Figure 59 Structure of tantalum–zinc alkylidyne complexes

of one tetraanionic tris(zincate) ligand of the dimeric complex. Owing to the special coordination situation and the presence of anionic charges, the Zn–C bond distances of the *gem*-dizincated carbons are rather long (2.15 Å) compared to the Zn–C bond distances found in dialkylzinc compounds (1.95 Å) or in the structure described before (2.03 Å). A comparable elongation of the Zn–C bond was found in the solid-state structure of different geminal organodimetallic compounds containing zinc and other metal. For example, the tantalum–zinc alkylidyne complexes presented in Figure 59 show bridging Zn–C bond lengths ranging from 1.11 to 1.15 Å, reflecting weak Zn–C interactions.<sup>247,248</sup>

## 6 REACTIVITY OF ORGANOZINC COMPOUNDS

(*See Organic Synthesis Using Metal-mediated Coupling Reactions*)

The reactivity of organozinc compounds with various reagents such as water, amines, alcohols, and  $\text{CO}_2$  has already

been mentioned in the preceding sections and will not be considered here.

## 6.1 Reactivity with CO

In contrast to Grignard reagents, dialkylzinc compounds are inert to carbon monoxide at atmospheric pressure either in the absence of solvents or in solution in THF, diglyme, ether, or benzene. Although Rathke and Yu reported in 1972 that the addition of potassium *tert*-butoxide in stoichiometric amounts promoted the absorption of carbon monoxide, it is now known that the actual reactive species was the corresponding zincate compound  $(R_2ZnO-t-Bu)^-K^+$ . The only zinc carbonyl species reported so far has been observed by  $^{13}C$  NMR studies of  $^{13}CO$  on zeolite ZnY and polycrystalline ZnO, at low temperature.<sup>249</sup> Before this report, such species were only suggested from infrared and photoelectron studies of CO weakly bound to ZnO.

## 6.2 Reactivity with O<sub>2</sub>

The high reactivity of organozinc compounds towards oxygen was already noted by Frankland, who reported some 150 years ago the formation of  $Zn(OEt)_2$  by the controlled oxidation of  $Et_2Zn$ .<sup>250</sup> Even if this reaction was successfully used to prepare alcohols and hydroperoxides (*see Peroxide*) in relatively good yields<sup>251</sup> (Scheme 16), the exact composition of the products and the reaction mechanism remain rather uncertain. In 1864, Lissenko proposed the formation of  $EtZnOEt$ ,<sup>252</sup> whereas Demuth and Meyer claimed some years later the isolation of the peroxide (*see Peroxide*)  $EtZnOOEt$ , a white powder resulting from the oxidation of  $Et_2Zn$  in ligroine.<sup>253</sup> However, subsequent studies agreed with rapid oxidation of both Zn–C bonds and formation of compounds with general formula  $(ROO)_2Zn$ ,  $ROZnOOR$  and  $(RO)_2Zn$ .<sup>254</sup>

Even if the free radical chain process shown in Scheme 17<sup>255</sup> was a commonly accepted mechanism, some very recent work published by Lewinski and coworkers strongly questions it. They initially reported the first zinc alkylperoxide structurally characterized by X-ray diffraction,

Scheme 16

Scheme 17

the dimeric  $[EtOOZn(BDI)]_2$  (BDI =  $\beta$ -diketiminate ligand) obtained in high yield and in a few minutes by reaction of  $EtZn(BDI)$  complex with  $O_2$  at  $0^\circ C$ .<sup>256</sup>

In 2003, the same group published a study of the reaction of  $O_2$  with the chelate complex  $[EtZn(azol)]_n$  (*azol* = 1-aziridineethanolate) and isolated the zinc ethylperoxide complex  $[EtOOZn(azol)]_2[EtZn(azol)]_2$  in 92% yield from the reaction in benzene<sup>257</sup> (Figure 60). The compound was found resistant to further oxidation with  $O_2$  and the reaction was significantly inhibited in THF solution. They also studied the controlled oxidation of  $Et_2Zn$  by  $O_2$ , which led to the compound  $Me_6Zn_7(OMe)_8$  in high yield. This compound is analogous to the product of methanolysis of  $Et_2Zn$  (Section ‘Structure’ and Figure 34), showing that selective oxidation of dialkylzinc compounds may be a route for the preparation of zinc alkoxides.

Various modes of oxygen-capture by lithiated organozinc reagents have been described in the sequential reaction of  $Me_2Zn$  with a 2-pyridylamine  $[HN(2-C_5H_4N)R]$ ,  $R = Ph, 3,5$ -xylyl, 2,6-xylyl, benzyl, Me], *t*-BuLi and afterward  $O_2$ .<sup>258</sup> The nature of the products was found to be dependent on R and suggested a competition between the oxophilicity of lithium and zinc (Scheme 18). When *N,N'*-diphenylbenzamidine (HAm) is used instead of 2-pyridylamine, and depending on the solvent conditions, the sequential reaction leads to various triorganozincate species.<sup>259</sup> While the product isolated from THF solutions is the dimer  $[THF\cdot Li(Me)OZnAm_2]_2$  corresponding to a formal insertion (*see Insertion*) of oxygen into the Zn–C bond, without donor solvent the polymer  $[(LiO-t-Bu)(MeZnO-t-Bu)_3]_n$  and the oxide-encapsulation complex  $(\mu_6-O)(Li_2ZnAm_3)_2$  were obtained.

## 6.3 Substitution Reactions

### 6.3.1 With Inorganic Halides

As a result of their low basicity and low reducing power, organozinc reagents are more suitable than the corresponding magnesium (*see Beryllium & Magnesium: Organometallic Chemistry*) or lithium (*see Alkali Metals: Organometallic Chemistry*) derivatives for the alkylation of some transition metal halides. For example, bis(trimethylsilylmethyl)zinc

Figure 60 Structure of the zinc ethylperoxide  $[EtOOZn(azol)]_2[EtZn(azol)]_2$

Scheme 18

$[(\text{Me}_3\text{SiCH}_2)_2\text{Zn}]$  and bis(neopentyl)zinc  $[(\text{Me}_3\text{CCH}_2)_2\text{Zn}]$  react with tantalum chloride ( $\text{TaCl}_5$ ) and niobium chloride ( $\text{NbCl}_5$ ) to give the corresponding alkyl metal chlorides of general formula  $\text{R}_n\text{MCl}_{5-n}$  ( $\text{M} = \text{Ta}$ ,  $n = 1-3$ ;  $\text{M} = \text{Nb}$ ,  $n = 2$ ;  $\text{R} = \text{Me}_3\text{SiCH}_2$ ,  $\text{Me}_3\text{CCH}_2$ )<sup>260</sup> (equation 55).

The oxidative alkylation of titanium compounds ( $\text{Cp}^*\text{TiX}$ ;  $\text{Cp}^* = \eta^5\text{-C}_5\text{Me}_5$ ,  $\text{X} = \text{Me}$ ,  $\text{OMe}$ ,  $\text{Cl}$ ,  $\text{N}=\text{CH-}t\text{-Bu}$ ) by dimethylzinc and dimethylcadmium has been reported to afford diamagnetic (*see Diamagnetism*) compounds of general formula  $\text{Cp}^*\text{TiMe(X)}$  and metallic zinc and cadmium, respectively.<sup>261</sup>

Organozinc halides and diorganozinc compounds smoothly alkylate chlorophosphane derivatives in THF at  $0^\circ\text{C}$  in good to excellent yields<sup>262</sup> (equation 56).

Addition of catalytic or stoichiometric quantities of  $\text{CuCN} \cdot (\text{LiCl})_2$  radically increases the reactivity of diorganozinc ( $\text{R}_2\text{Zn}$ ) and organozinc halide ( $\text{RZnX}$ ) compounds. The resulting copper–zinc species ( $\text{RCu(CN)ZnR}$  or  $\text{RCu(CN)ZnX}$ ) react with stannyl chlorides ( $\text{R}'_3\text{SnCl}$ ) to give the corresponding alkylated stannyl derivatives ( $\text{R}'_3\text{SnR}$ )

in high yields<sup>8</sup> (Scheme 19). It is worth mentioning that  $\text{Me}_3\text{SiCl}$  generally fails to react with either organozinc or zinc–copper compounds.

### 6.3.2 With Organic Halides

When diorganozinc and organozinc halide compounds react with allylic halides in the presence of  $\text{Cu}^{\text{I}}$  salts, the  $\text{S}_{\text{N}}2'$  (*see Nucleophilic Addition: Rules for Predicting Direction*) products are selectively obtained. In contrast, the reactions catalyzed by  $\text{Ni}^0$  or  $\text{Pd}^0$  lead to the  $\text{S}_{\text{N}}2$  products (Scheme 20).

The cross-coupling reaction between organozinc halides and alkenyl or aromatic halides is efficiently catalyzed by  $\text{Pd}^{\text{II}}$  or  $\text{Ni}^{\text{II}}$  salts. Organo-copper reagents derived from organozinc halide compounds react similarly with alkenyl halides but in harsh conditions (refluxing DME several days) to give the coupling products in a stereo-controlled way (Scheme 21). It has been found that the presence of an electron-withdrawing group ( $\text{NO}_2$ ,  $\text{COOR}$ ,  $\text{COR}$ ) in the  $\beta$ -position facilitates the substitution reaction via an addition-elimination mechanism. In contrast, the coupling reaction with 1-iodo- and 1-bromoalkynes takes

Scheme 19

Scheme 20

Scheme 21

place in mild conditions (−80 to 0 °C, few hours) (equation 57).

While the reaction of acid chlorides with organozinc halide compounds is relatively inefficient, the reaction with the corresponding copper–zinc reagents or the catalysis with Pd<sup>II</sup> salts represents a smooth route for the preparation of ketones in very good yields (equation 58).

The more difficult cross-coupling reaction between Csp<sup>3</sup>–Csp<sup>3</sup> can be accomplished by mixed zincate compounds, prepared by the reaction of diorganozinc derivatives with Me<sub>2</sub>CuMgCl·MgCl(CN) (equation 59). Substitution reaction at Csp<sup>3</sup> centers are also efficiently catalyzed by Ni<sup>II</sup> salts when the alkyl halide contains a double bond in remote position (Scheme 22). Changing the double bond for a triple bond leads to an intramolecular carbozincation reaction (equation 60).

#### 6.4 Addition to Carbonyl Compounds

In contrast to organomagnesium (*see Beryllium & Magnesium: Organometallic Chemistry*) and organolithium

(*see Alkali Metals: Organometallic Chemistry*) reagents, dialkylzinc compounds react only slowly with aldehydes to give addition products. Moreover, when the zinc compounds bear hydrogens in β-position a competitive reduction reaction can take place. Reduction is also the main reaction with ketones. Thus, the addition of organozinc derivatives with carbonyl compounds usually requires the presence of metal salts, Lewis acids (*see Lewis Acids & Bases*) [Ti(O-*i*-Pr)<sub>n</sub>Cl<sub>4-n</sub>, Me<sub>3</sub>SiCl, BF<sub>3</sub>·OEt<sub>2</sub>], donor ligands or auxiliaries. However, it has been shown that aryl-, vinyl-, and alkynylzinc reagents are more reactive than the saturated organozinc reagents. They react smoothly with carbonyl derivatives in the absence of catalysts. For example, alkenylzinc chlorides add to α-amino aldehydes to give unsaturated 1,2-amino alcohols with acceptable yields and good stereoselectivity (equation 61). More generally, highly reactive allylic zinc reagents add to a wide range of carbonyl functionalities. In contrast, the reaction of propargylic zinc derivatives with aldehydes or ketones always give mixtures of rearranged products.

The research on asymmetric organozinc additions to carbonyl compounds started in 1984 when Oguni and Omi obtained 49% e.e. in the reaction of diethylzinc with benzaldehyde catalyzed by (*S*)-leucinol. Since then, a huge number of chiral (*see Chiral*) catalysts, mostly derived from amino alcohols, have been developed and the subject has been extensively reviewed.<sup>263,264</sup> The first highly enantioselective (*see Electrophile*) ligand (−)-3-exo-dimethylaminoisoborneol [(−)-DAIB] developed by Noyori and coworkers in 1986 is still used even if its application is mostly limited to aromatic and heteroaromatic aldehydes (equation 62). As shown by previous studies, chiral (*see Chiral*) ligands have a dual

Scheme 22

function: they control the stereochemistry of the organozinc addition and increase the nucleophilicity (*see Lewis Acids & Bases*) of the alkyl groups bound to zinc through their coordination to the zinc center.

The amino-alcohol promoted addition of dialkylzinc to aldehydes has been extensively studied and several types of transition states have been proposed (Figure 61 and 62). Some years ago, Yamakawa and Noyori characterized two tricyclic transition states (*syn*- and *anti*-orientation) and suggested the mechanism shown in Scheme 23.<sup>265</sup> In the first step, a complex between  $\text{Me}_2\text{Zn}$  and  $(-)\text{DAIB}$  is formed. This complex, which has no alkylating properties, further coordinates a second  $\text{Me}_2\text{Zn}$  molecule through the oxygen atom. After that, a benzaldehyde molecule coordinates to the former zinc atom in *anti* position with respect to the chiral (*see Chiral*) ligand. A following methyl migration to the *si* face of the aldehyde produces the asymmetric center. Finally further reaction with  $\text{Me}_2\text{Zn}$  can regenerate the bis(dimethylzinc)- $(-)\text{DAIB}$  complex and liberate  $(S)\text{-(1-phenyl)ethoxy-ZnMe}$  which gives  $(S)\text{-1-phenylethanol}$  under aqueous workup.

Theoretical investigations have shown that the most favored tricyclic transition state has the *anti*-configuration, which is  $12\text{--}13\text{ kJmol}^{-1}$  more stable than the *syn*-configuration and  $29\text{ kJmol}^{-1}$  more stable than the bicyclic transition state (Figure 61). However, few years later Rasmussen and Norrby<sup>266</sup> could characterize two new six-membered transition states, *env* and *chair* (Figure 62), which are lower in energy (respectively by 19 and  $50\text{ kJmol}^{-1}$ ) than the more stable *anti* form characterized by Yamakawa and Noyori.

Interestingly, it was found that this reaction shows a large positive nonlinear effect with the enantiomeric purity of the DAIB ligand. In other words, higher enantioselectivity is obtained with lower enantiomeric purity of the ligand. For example, when diethylzinc was added to benzaldehyde in presence of DAIB with 100% e.e., the addition product was obtained in 98% e.e., whereas DAIB with only 15% e.e. led to the addition product with 95% e.e. In addition, if a racemic DAIB mixture was used instead of an enantiomerically pure ligand, the reaction rate was reduced by 13 times. This behavior can be explained by the formation of two different dimeric species, in the first step of the reaction, when DAIB is not enantiomerically pure, that is, the homodimer  $[\text{RZn}\{(-)\text{DAIB}\}]_2$  with  $C_2$  symmetry and the heterodimer with  $C_i$  symmetry, which was found to be the more stable and less reactive one (Figure 63). Thus, the observed nonlinear effect comes from the consumption of the minor enantiomer through formation of the stable and faintly reactive heterodimer.

In 1995, Soai and coworkers reported a highly enantioselective asymmetric autocatalysis of pyrimidyl alkanol in the enantioselective addition reaction of  $i\text{-Pr}_2\text{Zn}$  to pyrimidine-5-carboxaldehyde<sup>267</sup> (equation 63). When a 5-pyrimidyl alkanol with a small enantiomeric excess such as  $5 \times 10^{-5}\%$  is added to  $i\text{-Pr}_2\text{Zn}$  and pyrimidine-5-carboxaldehyde, then the reaction

Scheme 23

gives the alkanol of the same absolute configuration with up to 99.5% e.e. The autocatalytic feature of the reaction has been proven by recent kinetic analysis<sup>268</sup> (see *Kinetic Methods*).

Recently, it has been found that shifting the NMe<sub>2</sub> moiety in (–)-DAIB to a morpholine group (MIB) gives a much more stable derivative, which also displays a wider reactivity<sup>269</sup>

**Figure 62** New transition states characterized by Rasmussen and Norrby

(equation 64).

In addition to amino alcohols, numerous other ligands such as amines, amino thiols, diols, disulfides, and diselenides have been developed and tested. Several have shown a very good enantioselectivity for dialkylzinc additions to a variety of aldehydes. In contrast, the addition of aryl-, vinyl-, and alkynylzinc compounds was not so extensively studied and more work is still needed in

**Figure 61** Transition states characterized by Yamakawa and Noyori

**Figure 63** Structure of the homo- and heterodimer [RZn(DAIB)]<sub>2</sub>

**Figure 64** Structure of some enantioselective ligands for vinyl- and alkynylzinc additions to aldehyde

this area. Nevertheless, some highly enantioselective catalysts have been recently obtained.<sup>264</sup> For example,  $\text{Ph}_2\text{Zn}$  reacts with propionaldehyde in the presence of 10 mol % of the chiral (*see Chiral*) binaphthyl ligand (*R*)-3,3'-bis(2'',5''-dihexyloxyphenyl)-1,1'-binaphthol to give (*S*)-1-phenylpropanol with 87% e.e. (equation 65). The spiroitanate complex  $(\text{TADDOLate})_2\text{Ti}$  ( $\text{TADDOLate} = \alpha, \alpha, \alpha', \alpha'$ -tetraaryl-1,3-dioxolane-4,5-dimethanolate) was reported to give 84% e.e. in the reaction of divinylzinc with benzaldehyde. Even higher e.e., up to 92%, have been obtained for the addition of diisopropenylzinc to aromatic aldehydes catalyzed by proline based ligands such as DPMPM [diphenyl(1-methylpyrrolidin-2-yl)methanol] and ephedrine based ligands (Figure 64). Addition of stoichiometric amounts of *N*-methylephedrine to the reaction of terminal alkynes with different aromatic and aliphatic aldehydes containing  $\alpha$ -substituents led to very high enantioselectivity.

Compared to the well-developed organozinc addition to aldehydes, the related addition to ketones has been far less studied. However, the first catalytic addition of dialkylzinc to ketones has been achieved few years ago using camphorsulfonamide alcohols ligands and  $\text{Ti}(\text{O-}i\text{-Pr})_4$  salt (equation 66). In the same year, it was also discovered that 15 mol % of (+)-DAIB catalyze the diphenylzinc addition to ketones to generate chiral (*see Chiral*) tertiary alcohols with up to 91% e.e. (equation 67).

## 6.5 Addition to C=N bonds

The development of organozinc addition reactions to imines and imine derivatives has been somewhat limited by both the poor electrophilicity of the azomethine carbon and the low reactivity of organozinc reagents.

Even the very efficient enantioselective catalysts used in organozinc addition reactions to carbonyl compounds failed to catalyze the corresponding addition reactions to nonactivated imines such as *N*-silyl-, *N*-phenyl-, or *N*-benzyl-imines. However, enantioselective additions of dialkylzinc compounds to more activated imines, like *N*-acyl- or *N*-phosphinoyl-imines, in the presence of catalytic or stoichiometric amounts of chiral (*see Chiral*) aminoalcohols, have been recently reported. For example, in presence of 1 equiv of (*N,N*-dibutylnorephedrine) (DBNE) diethylzinc reacts with masked *N*-acyl imines like *N*-(amidobenzyl)benzotriazoles, to give chiral *N*-(1-phenylpropyl)amides with up to 76% e.e.<sup>270</sup> (equation 68).

*N*-diphenylphosphinoyl imines also react with dialkylzinc in the presence of stoichiometric or catalytic amounts of different chiral (*see Chiral*) ligands<sup>271</sup> (Scheme 24). Acid hydrolysis of the resulting phosphinamides occurs without racemization and gives enantiomerically enriched primary amines. The allylation of various cyclic imines was obtained with high enantioselectivity (*see Electrophile*), 77 to 99% e.e., in the presence of lithiated bis-oxazoline ligands (Scheme 25).

Scheme 24

Scheme 25

## 6.6 Reactions with Carbon–Carbon Multiple Bonds

Saturated organozinc halides are usually unreactive towards alkenes and nonterminal alkynes, but as already mentioned in previous reactions, allylic zinc derivatives were found to be more reactive towards such functionalities. Furthermore, the reactivity of diorganozinc derivatives can be enhanced by the use of polar (see *Polar Compounds*) solvents, or the addition of diverse Lewis acids<sup>8,9,262</sup> (see *Lewis Acids & Bases*). For example, conjugate addition reactions (or 1,4-additions) involving a variety of double bonds in conjugation with an electron-withdrawing group (EWG) work well in *N*-methylpyrrolidine (NMP) and in the presence of  $\text{Me}_3\text{SiX}$  (equation 69). A 1,4-addition pathway is also observed in the reaction of diorganozinc compounds with cyclic enones (equation 70). Even if only one of the two R groups is transferred to the substrate, mixed organozinc compounds bearing a nontransferable group such as  $\text{R-Zn-CH}_2\text{SiMe}_3$  are usually preferred in order to avoid the waste of an R group.

Cyclic enones were also found to react with alkynylzinc halides in the presence of *tert*-butyldimethylsilyl triflate (equation 71).

The addition of diorganozinc compounds to alkynes can be promoted by different metallic species such as  $\text{Cp}_2\text{ZrI}_2$  and  $\text{Ni}(\text{acac})_2$  to give the corresponding vinylic zinc compounds (equation 72). A subsequent hydrolysis leads to the alkene, whereas iodinolysis provides the vinyl iodide derivative. Copper–zinc species, readily obtained by the

reaction of organozinc compounds with the THF soluble copper salt  $\text{CuCN} \cdot 2\text{LiCl}$ , add to a variety of conjugated alkenes and alkynes with 1,4-regioselectivity (see *Regioselectivity*) (Scheme 26). Addition to conjugated unsaturated aldehydes usually needs the presence of a Lewis acid catalyst, which nature also determines the regioselectivity (see *Regioselectivity*) of the reaction. While  $\text{Me}_3\text{SiCl}$  promotes 1,4-additions, reactions with  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  lead only to 1,2-addition products. It is worth mentioning that the 1,2-addition pathway was also observed in the reaction of diallylzinc with both linear and cyclic enones (Scheme 27). The peculiar dynamic properties of allylic zinc compounds (see Section 2.3.2) may be the origin of this behavior.

Organozinc addition reactions to unsaturated systems lead to an intermediate zinc compound which is in most cases further hydrolyzed to give the corresponding protonated organic compound. This intermediate can also be trapped by reaction with electrophiles (see *Electrophile*) ( $\text{E}^+$ ) such as aldehydes, acyl chlorides, organic halides, silyl halides, and so on. Depending on the nature of the electrophile (see

*Electrophile*) used, zinc enolate intermediates obtained in organozinc addition to enones can be either *O*-trapped or *C*-trapped (Scheme 28).

## 6.7 The Simmons–Smith Reaction

The original Simmons–Smith reaction is a cyclopropanation reaction of olefins, achieved by an ethereal solution of a zinc–copper couple and diiodomethane<sup>272</sup> (equation 73). It is without doubt one of the most important applications of organozinc reagents in organic synthesis. Its synthetic value emerges from the following features: mild conditions; broad generality with regard to the olefin structure; stereospecificity with respect to the olefin geometry; stereoselectivity with allylic alcohols, acetals, and enol ethers (equation 74). Furthermore, although some insertion (see *Insertion*) of methylene groups into the  $\alpha$ -C–H bond of the ethereal solvent occurs, insertion into vinylic C–H bond has never been observed.

Scheme 26

Scheme 27

Scheme 28

Over the past 40 years, several modifications of the original procedure have been reported. Wittig and coworkers first reported that carbenoid reagents of the type  $XCH_2ZnX$  or  $(XCH_2)_2Zn$  could also be prepared by the reaction of  $Zn^{II}$  salts with diazoalkane.<sup>273</sup> Later, a significant improvement was made by Furukawa when he found out that diethylzinc could advantageously replace activated zinc in the reaction with diiodomethane.<sup>274</sup> This procedure, in contrast to the original one, allows the preparation of substituted carbenoid reagents (equation 75). More recently, it was shown that (chloromethyl)zinc reagents are generally more reactive than the (iodomethyl)zinc analogues when 1,2-dichloroethane was used as the solvent.<sup>275</sup>

A detailed comprehension of the mechanism and the exact structure of the species responsible for the cyclopropanation are still the subject of controversies. Since the participation of free carbenes (*see Carbene Complexes*) is unlikely, the reagents are frequently referred to as carbenoids. Simmons and Rickborn first proposed that  $(ICH_2)_2Zn \cdot ZnI_2$ , resulting from the Schlenk equilibrium of  $ICH_2ZnI$ , was the reactive species, whereas Dauben concluded from his studies that  $ICH_2ZnI$  should be responsible for the cyclopropanation. Relating to the system  $Et_2Zn/CH_2I_2$ , Furukawa took an intermediate position when he stipulated that 'the active species may include  $EtZnCH_2I$ ,  $ICH_2ZnI$  and/or  $Zn(CH_2I)_2$  or associated complexes containing these molecules'.<sup>276</sup> In fact, during the past decade the solid-state structure of both  $ICH_2ZnI \cdot L$  and  $Zn(CH_2I)_2 \cdot L$  ( $L$  = crown ether, glycol bis-ether) has been unambiguously characterized by X-ray crystallography (see Section 2.4.1 Table 4 and Section 3.1.2 Table 7). Moreover, Charette and Marcoux could differentiate the three reagents

$EtZnCH_2I$ ,  $ICH_2ZnI$  and  $(ICH_2)_2Zn$  by low-temperature  $^{13}C$  spectroscopy in  $CD_2Cl_2$  and in the presence of a chiral (*see Chiral*) complexing agent.<sup>277</sup> In these conditions, they found that  $ICH_2ZnI$  did not rearrange in  $ZnI_2$  and  $(ICH_2)_2Zn$ , and also that the Furukawa's reagent  $EtZnCH_2I$  was in equilibrium with  $Et_2Zn$  and  $(ICH_2)_2Zn$ . Finally, it is interesting to note that Charette reported few years ago a storable complex, bipyridine- $Zn(CH_2I)_2$ , which could efficiently cyclopropanate olefins upon addition of  $ZnI_2$ .

An investigation of the potential energy surface for the model reaction between ethylene and  $ClCH_2ZnCl$  reveals the existence of two reaction pathways:<sup>278</sup> the addition process (leading to the cyclopropane product) and the insertion (*see Insertion*) process (leading to the cyclopropene product). However, the energy barrier for the addition process ( $24.75 \text{ kcal mol}^{-1}$ ) is found to be smaller than for the insertion process ( $36.01 \text{ kcal mol}^{-1}$ ). Thus, at this point both computational and experimental results agree in that the addition pathway is favored and the insertion (*see Insertion*) negligible. This theoretical study also validates the three-centered transition state first suggested by Simmons to account for the stereochemical features of the reaction (Figure 65).

The last few years have seen some development in the preparation of carbenoid reagents. In 1998, Shi and coworkers reported that a new class of (iodomethyl)zinc compounds ( $RXZnCH_2I$ ), readily obtained by the reaction of  $RXH$  ( $ROH$ ,  $RCO_2H$ ) with  $RZnCH_2I$ , can efficiently cyclopropanate olefins.<sup>279</sup> The carbenoid reactivity was found to increase with the acidity of  $RXH$ . For example,  $CF_3CO_2ZnCH_2I$

**Figure 65** Transition states in the cyclopropanation of ethylene with mono zinc carbenoids (a) and with *gem*-dizinc carbenoids (b)

could cyclopropanate *trans*- $\beta$ -methylstyrene at room temperature within 30 min<sup>280</sup> (equation 76). Two years later, Charette showed that ethylzincmethyl perfluoropentanoate ( $\text{C}_4\text{F}_9\text{CO}_2\text{CH}_2\text{ZnEt}$ ), obtained quantitatively by the reaction of diethylzinc with iodomethyl perfluoropentanoate is a highly reactive carbenoid reagent owing to internal Lewis acid (see *Lewis Acids & Bases*) activation<sup>281</sup> (equation 77). This acyloxymethylzinc compound can cyclopropanate poorly reactive alkenes, such as *trans*-stilbene, in moderate yield. In addition, from  $^1\text{H}$  NMR and GC analysis he attributed the improved reactivity of Shi's reagent ( $\text{CF}_3\text{CO}_2\text{ZnCH}_2\text{I}$ ) to the in situ (see *In Situ Reaction*) formation of the corresponding acyloxymethylzinc ( $\text{CF}_3\text{CO}_2\text{CH}_2\text{ZnI}$ ) (Scheme 29).

Alkylbenzenes undergo a remarkable ring expansion reaction with zinc carbenoid reagents derived from  $\text{CHI}_3$ ,

which results in the formation of cycloheptatrienyl derivatives (Scheme 30). In 2002, the group of Charette reported that  $\text{CHI}_3$  reacts with  $\text{Et}_2\text{Zn}$  or  $\text{EtZnI}$  at  $0^\circ\text{C}$  to form *gem*-dizinc carbenoids with general formula  $\text{ICH(ZnR)}_2$  ( $\text{R} = \text{Et, I}$ ) which are very reactive and provide access to substituted cyclopropanes in excellent yields.<sup>282</sup> A density functional theory investigation for the cyclopropanation of ethylene has shown that these *gem*-dizinc carbenoids, compared to their corresponding mono zinc carbenoids, react with lower barriers to reaction (about  $15 \text{ kcal mol}^{-1}$ ) which can further be lowered upon addition of  $\text{ZnI}_2$  as a Lewis acid.<sup>283</sup> The authors also identified transition states on the way to cyclopropanation products for the reaction of *gem*-dizinc carbenoids with  $\text{C}_2\text{H}_2$  which present the general schematic structure shown in Figure 65.

A novel application of Simmons–Smith reagents designed for the epoxidation of carbonyl compounds has been reported a few years ago<sup>284</sup> (Scheme 31). The zinc reagents react with sulfides to give the corresponding sulfur ylides, which are then used to generate epoxides from aldehydes. The reaction takes place in mild conditions and works well with aromatic or aliphatic aldehydes. It is interesting to note that unsaturated aldehydes also give the epoxidation compound without undergoing cyclopropanation.

## 6.8 The Reformatsky Reaction

In its original version the so called Reformatsky reaction was the preparation of  $\beta$ -hydroxy esters, or their dehydration products, by reacting a mixture of activated zinc, an  $\alpha$ -bromo ester and a carbonyl compound in ethereal

Scheme 29

Scheme 30

Scheme 31

solvent with subsequent hydrolysis (equation 78). The reaction between zinc and the  $\alpha$ -halo ester generates in situ (*see In Situ Reaction*) an organozinc species which further reacts with the aldehydes or ketones to give the corresponding  $\beta$ -hydroxy ester. However, the actual synthesis is typically carried out in two stages with the previous formation of a zinc enolate derivative followed by the addition of a carbonyl compound. The reaction has been extended to other  $\alpha$ -halogeno compounds, such as  $\alpha$ -halo-nitriles and -amides, and to a large variety of substrates.

There has been considerable discussion concerning the nature of the Reformatsky reagent with suggestions for an *O*-metalated species or alternatively a *C*-metalated species. However, as shown by the solid-state structure of  $[\text{BrZnCH}_2\text{CO}_2\text{-}t\text{-Bu}(\text{THF})]_2$  the real situation is best described as a combination of both species (*see* Section 3.1.2 Figure 30 and Section 3.2.2).

An underlying problem associated with the traditional procedure, which uses zinc dust, is the low reactivity of this metal towards  $\alpha$ -halo esters; consequently initiation of the reaction requires an activation of zinc such as Rieke zinc, Zn–Cu couple, Zn/Ag–graphite or Zn/Hg amalgam. It has been shown recently that high-intensity ultrasound (*see Sonication*) irradiation of the reaction mixture in presence of  $\text{I}_2$  leads to very high yields in short reaction time, without activation of zinc and even using undistilled reagent-grade dioxane.<sup>285</sup> A variety of other low-valent metals (Ba,<sup>286</sup> Mg, Cd, Ni, In, Ce, Li,  $\text{FeCO}_5$ ) or metal derivatives such as  $\text{Cp}_2\text{TiCl}$ ,<sup>287</sup>  $\text{Li}[\text{Bu}_2\text{SnI}_3]$ ,<sup>288</sup>  $\text{SmI}_2$ ,<sup>289,290</sup> can efficiently substitute zinc dust. However, because of their susceptibility to oxidation and hydrolysis these reagents need to be freshly prepared. Therefore, efforts are now focused on developing catalytic versions of the Reformatsky reaction. For example, it was found that a number of metal salts such as  $\text{RhCl}(\text{PPh}_3)_3$ ,<sup>291</sup>  $\text{CeCl}_3$ ,<sup>292</sup>  $\text{Cp}_2\text{TiCl}_2$ <sup>293</sup> allow inter- and intramolecular Reformatsky reactions to be achieved under mild condition and with better yields.

In most cases, the Reformatsky reaction is not very stereospecific and mixtures of *erythro*- and *threo*- $\beta$ -hydroxyesters are obtained when asymmetric  $\alpha$ -haloesters are used as reagents (equation 79). The *erythro*:*threo* ratio appears to depend on the solvent polarity and the reaction time. However, it is of current interest to develop highly stereocontrolled asymmetric Reformatsky reactions. To date, high diastereoselectivities could be achieved only in a few cases either by substitution of zinc with other metal

salts<sup>288,289,290</sup> or by addition of chiral (*see Chiral*) ligands.<sup>294</sup>

## 6.9 Oligomerization and Polymerization (*See Oligomerization & Polymerization by Homogeneous Catalysis*)

Organozinc compounds are efficient catalysts in the polymerization of vinylic monomers, but they have found more applications as catalysts/initiators for ring opening polymerization of heterocyclic monomers<sup>295</sup> such as lactides,<sup>296</sup> lactones, and epoxides<sup>297</sup> (Scheme 32). The organozinc derivatives are usually combined in various stoichiometries with cocatalysts like water, alcohols, carboxylic acid, or amines. The active catalysts are proposed to be complexes with general formula  $\text{L}_n\text{ZnX}$ , where X is an active initiating group such as OR,  $\text{NR}_2$ , or alkyl, and  $\text{L}_n$  is a ligand that coordinates the  $\text{Zn}^{\text{II}}$  center. As shown in Scheme 32 for the copolymerization of  $\text{CO}_2$  and epoxides and in Scheme 33 for the polymerization of lactides, it is generally accepted that the reaction occurs via coordination of a monomer to the coordinatively unsaturated zinc center of the catalyst, followed by insertion (*see Insertion*) into the Zn–X bond.

During the last decade, the design and synthesis of new ligands for specific polymerization reactions has been the focus of much interest. Among the different ligands tested so far,  $\beta$ -diiminates (*see* Section 3.4.1) have shown the highest activity reported for the copolymerization of  $\text{CO}_2$  and epoxides.<sup>179</sup>

When chiral (*see Chiral*) complexes are used as catalysts, they can exhibit some diastereoselectivity. For example, optically active polycarbonates have been prepared by asymmetric copolymerization of cyclohexene oxide and carbon dioxide in the presence of a mixture of  $\text{Et}_2\text{Zn}$  and a chiral amino alcohol<sup>298</sup> (Scheme 34). Even achiral complexes have been found to exhibit some diastereoselectivity in polymerization reactions. For instance, monomeric  $\text{Zn}^{\text{II}}$  complexes with tris(pyrazolyl- and indazolyl-)hydroborate ligands (*see* Section 3.4.2) polymerize preferentially *meso*-lactide over D-lactide and L-lactide in  $\text{CH}_2\text{Cl}_2$  at 22 °C.<sup>299</sup> The compound  $\text{EtZnN}(t\text{-Bu})\text{ZnEt}$ , which is easily prepared by reaction of  $\text{Et}_2\text{Zn}$  with  $t\text{-BuNH}_2$ , was found to be an excellent catalyst for the stereospecific polymerization of propylene oxide.<sup>300</sup>

The construction of chiral (*see Chiral*) zinc complexes in order to perform stereoselective polymerizations has

Scheme 32

Scheme 33

Scheme 34

been recently undertaken by Chakraborty and Chen.<sup>301</sup> They have found that the tetranuclear complex  $\{(\pm)\text{-trans-Cy}(\text{NSiMe}_3)_2\}_2\text{Zn}_4\text{Et}_4$  and the dinuclear complex  $\{(\pm)\text{-trans-Cy}(\text{NHSiMe}_3)(\text{NSiMe}_3)\}_2\text{Zn}_2\text{Et}_2$  are obtained in good yields from the reaction of racemic  $(\pm)\text{-trans-1,2-(NHSiMe}_3)_2\text{-cyclohexane}$  ( $(\pm)\text{-trans-cy}(\text{NHSiMe}_3)_2$ ) with two equiv of  $\text{Et}_2\text{Zn}$  and one equiv of  $\text{Et}_2\text{Zn}$ , respectively. In both cases, only one diastereomer was formed and its molecular structure determined by X-ray crystallography (Figure 66). Whereas the two complexes were shown to be efficient initiators for polymerization of  $\epsilon$ -caprolactone and L-lactide, only the tetranuclear complex was efficient for the polymerization of methyl methacrylate upon activation with  $\text{Al}(\text{C}_6\text{F}_5)_3$ .

Cationic organozinc compounds are expected to be good catalysts for ring opening polymerization reactions of epoxides and lactones because the enhanced Lewis acidity (*see Lewis Acids & Bases*) of the zinc center favors its coordination to the monomer. For example, Walker and coworkers have found that the cationic zinc substituted cyclopentadienyl complex  $[3,5\text{-Me}_2\text{C}_6\text{H}_3\text{CH}_2\text{CMe}_2\text{C}_5\text{H}_4\text{Zn}(\text{TMEDA})]^+ [\text{EtB}(\text{C}_6\text{F}_5)_3]^-$  is an active initiator species for the polymerization of cyclohexene oxide and  $\epsilon$ -caprolactone.<sup>302</sup>

## 6.10 Reactivity of *Gem*-Dimetallic Species

Organo-*gem*-dimetallic compounds that possess two nucleophilic (*see Lewis Acids & Bases*) sites on one carbon atom

Figure 66 Structures of  $\{(\pm)\text{-trans-Cy}(\text{NSiMe}_3)_2\}_2\text{Zn}_4\text{Et}_4$  and  $\{(\pm)\text{-trans-Cy}(\text{NHSiMe}_3)(\text{NSiMe}_3)\}_2\text{Zn}_2\text{Et}_2$

can undergo multiple transformations in one-pot reactions and form two new C–C bonds. This is particularly attractive for organic chemists who need new strategies with a minimum of chemical steps for the building of complex molecules. In recent years, *gem*-dizincio reagents in particular have been the focus of much interest because their relative stability and moderate reactivity, compared to the related *gem*-dilithio and -dimagnesium derivatives, permit the control of both chemoselectivity and stereoselectivity during the transformations. The synthesis and synthetic applications of 1,1-*sp*<sup>3</sup> and 1,1-*sp*<sup>2</sup> organodimetallic derivatives have been specifically covered in two different reviews.<sup>245,246</sup>

The simplest *gem*-dizincio alkane bis(iodozincio)methane [CH<sub>2</sub>(ZnI)<sub>2</sub>] reacts with aldehydes, and with ketones in presence of a suitable activator or catalyst, to produce the corresponding olefinated compounds in good yields (equation 80). It has been shown that the nucleophilicity of the zinc atom in CH<sub>2</sub>(ZnI)<sub>2</sub> can be enhanced by coordination of a heteroatom from a ligand or a solvent. Substrates which contain a suitably placed donor atom also lead to activation. For example, 1,2-diketones (see *Diketones*) such as benzil (PhCO-COPh) undergo efficient [2+1] cycloaddition reactions with CH<sub>2</sub>(ZnI)<sub>2</sub><sup>303</sup> (equation 81). The reaction is stereoselective, leading only to *cis*-diol derivatives.

R<sub>1</sub> = R<sub>2</sub> = Alkyl or R<sub>1</sub> = H, R<sub>2</sub> = Alkyl

Substituted *gem*-dimetallic compounds, readily obtained via allylation of alkenyl organometallics, react with aldehydes in the presence of BF<sub>3</sub>·Et<sub>2</sub>O but do not react with ketones. When alkylidenemalonates are used instead of aldehydes, the *Z*-olefins (see (*E*) & (*Z*) *Isomers*) are obtained with a very high stereoselectivity (Scheme 35). A transmetallation reaction with copper cyanide significantly increases the reactivity of *gem*-dimetallic derivatives via formation of 1,1-zinca cyanocuprates. Indeed, when these compounds react with

alkylating or allylating reagents, they give products of double alkylation or allylation (equation 82).

When *gem*-dimetallic reagents contain zinc and a metal of different nature MX<sub>n</sub> (MX<sub>n</sub> = MgBr, Li), they can react successively with two different electrophiles (see *Electrophile*) E<sub>1</sub><sup>+</sup> and E<sub>2</sub><sup>+</sup>, with the more reactive C–M bond reacting first (Scheme 36). Consequently, the vinylation of 1,1-borio zincioalkanes, catalyzed by Pd<sup>II</sup> salts, is an excellent procedure for the preparation of reactive allylboranes (equation 83).

A strong intramolecular chelation (see *Chelate Effect*) of a donor group to one of the zinc atoms leads to a good selectivity between the two metallic centers in sequential addition reactions, and also leads to a good diastereoselective reactivity of the organo-*gem*-dimetallics. As seen in Section 5.1 concerning allylmetalation of vinyl organometallic compounds, the intramolecular coordination of a basic atom (sulfur < oxygen < nitrogen) to the metal of the starting vinyl reagent allows the creation of two stereogenic centers in the resulting *gem*-dimetallic derivatives. Thus, a third stereogenic center can be produced by diastereoselective reactivity of the two metals (Scheme 37). Nevertheless, it was shown that the stereoselectivity depends strongly on the nature of the first electrophile (see *Electrophile*) used.

When the intramolecular chelating group (see *Chelating Ligands*) is a methoxy-methyl-ether (MOM) in  $\gamma$ -position, an

Scheme 35

Scheme 36

Scheme 37

internal nucleophilic substitution occurs at room temperature and products of cyclopropanation are obtained in good yields (equation 84).

The reactivity of *gem*-dizincioalkenes (prepared by metal allylation of alkynyl metals (see Section 5.1)) with aldehydes leads to the corresponding allene derivatives in moderate yields (Scheme 38). As already seen for *gem*-dizincioalkanes, an internal chelation of the 1,1-dimetalloalkene with a Lewis functional group allows differentiation of the reactivity of the two metal centers towards electrophile (see *Electrophile*) reagents. Scheme 39 summarizes the reactivity

Scheme 38

Scheme 39

of 1,1-dizincioalkene compounds containing a *tert*-butylether group in  $\gamma$ -position.

*gem*-Dizincioalkenes derivatives containing a suitably placed alkyl halide group can also be used for the synthesis of cyclobutene and cyclopentene compounds via intramolecular (*see Intramolecular*) nucleophilic substitution reactions (equation 85).

## Glossary

*Homoatomic:* same element

*Pnictide:* group 15 anion

*Pnicogen:* group 15 element

## Abbreviations

A<sup>I</sup> = Alkali metal; A<sup>II</sup> = alkaline earth metal; en = Ethylenediamine; crypt = 4,7,13,16,21,24-hexaoxa-1,10-diazatricyclo[8.8.8]hexacosane; Pn = Group 15 element (pnictogen).

## 1 INTRODUCTION

Zintl phases make up a class of compounds which are electronically positioned between the class of intermetallic compounds and insulating valence compounds.<sup>1</sup> These compounds are made up of electropositive elements from groups 1, 2 that, in a formal sense, donate their electrons to the electronegative elements from groups 13, 14, and 15, which use them to form the correct number of bonds such that each element has a filled shell. A more succinct definition of Zintl compounds is that they are normal valence compounds in which there is both ionic and covalent bonding. If the anionic units have enough electrons, they will form isolated anionic atoms. If there are not enough electrons to provide a closed shell of electrons (eight total for a main group element), then the main group element forms two-center–two-electron bonds. Zintl compounds are normally considered to be semiconductors, although the class also includes compounds whose structures can be described by the Zintl concept and are metallic. Pearson<sup>2</sup> classifies these as a subset of intermetallics that obey the rules of valence;

however, they are better classified as Zintl phases.<sup>3</sup> Because of the ionic nature of bonding between the cations and anions in Zintl compounds, they are soluble in polar, basic solvents. Anionic clusters of the heavier main group elements isolated from reactions of Zintl phases are known as Zintl anions.<sup>4,5</sup> The reactivity of these anions has been explored and this work has produced new cluster compounds<sup>6–12</sup> as well as novel materials.<sup>13–18</sup>

The description of bonding within these compounds has been treated by several different approaches that come to the same conclusion. The (8 – N) rule that is generalized by Mooser and Pearson<sup>19–21</sup> uses a covalent model with collective counting of electrons. The generalized 8 – N rule can be easily defined for simple binary compounds of the general formula, M<sub>m</sub>X<sub>x</sub> as 8x electrons are required in order to achieve the octet shells for the x X atoms. The valence electron count, VEC(X) can be defined as the total number of all valence electrons in relation to the number of the anionic atoms:  $VEC(X) = [m \cdot e(M) + x \cdot e(X)]/x$ , where an M atom has e(M) valence electrons. If covalent bonds exist between M atoms, the M atoms cannot donate all of their electrons and if covalent bonds exist between X atoms, the X atoms require fewer electrons. Typically, there are no bonds between M for a Zintl phase, and bonds are formed between X. The number of bonds, b(XX), can be accounted for in the equation and results in the equation:  $b(XX) = 8 - VEC(X)$ .<sup>22</sup> Zintl<sup>23</sup> and Klemm<sup>24</sup> examine local configurations in a setting of formal ions. Once the formal charges are assigned, the anionic lattice can be described as a pseudoelement that exhibits structural chemistry closely related to the isoelectronic element. The definition of a Zintl phase has undergone several revisions and has been expanded to include ternary<sup>25–27</sup> and transition metal compounds.<sup>27–32</sup> Although the bonding description originally proposed by Zintl has been augmented and is sometimes referred to as the Zintl-Klemm concept,<sup>33</sup> or Zintl-Klemm-Busmann concept,<sup>25</sup> the term Zintl concept is generally considered to be inclusive of those revisions. For transition metals, an estimation of the number of electrons which are localized on the metal and do not take part in the bonding must be considered, as described by Pauling.<sup>34</sup> Since bonding descriptions are effective only to the extent that they adequately relate structure and properties, only those transition metal compounds that are understood according to the Zintl model will be described herein. The reactivity and uses of Zintl phases for the synthesis of Zintl ions, new compounds, and novel materials by means of solution chemistry will also be presented.

## 2 BACKGROUND

Compounds of alkali and alkaline earth metals with elements of groups 16 and 17 are usually described as ionic compounds or salts with respect to their physical and chemical

properties, as well as their structures. The compounds with elements of groups 14 and 15 become increasingly metallic with increasing atomic number of the electronegative element and occur in stoichiometries not readily described by valence rules.<sup>20</sup> Many of these compounds were thought to be best classified as intermetallics. Hume-Rothery phases are certain alloys with the structures of different types of brass. Hume-Rothery found that valence electron concentration (number of valence electrons)/(number of atoms) dictated the structure. Shortly after the presentation of the Hume-Rothery rules concerning the relationship of electron concentration to crystal structure in intermetallic phases,<sup>35</sup> Eduard Zintl proposed that a subgroup of the intermetallic compounds were, in fact, not well represented within the descriptions of intermetallic phases. Zintl had prepared a number of alkali and alkaline earth metal groups 13, 14, and 15 binaries and investigated their structures.<sup>23</sup> The majority of these phases adopt the  $\beta$ -brass structure, while some crystallize in the NaTl structure type, both derivatives of the W structure. Hume-Rothery rules predicted an optimal electron concentration of  $3/2e^-$  per atom for compounds crystallizing in this structure type, but most of these compounds show electron concentrations of  $(1-5/2)e^-$  per atom. In addition, for these phases, significant contraction of the volume compared to the volume of the elements occurs; this is attributed to the ionic interactions between the electropositive and electronegative element that forms the correct number of homoatomic bonds, such that each element has a complete octet. The prototype Zintl compound, NaTl, could be described by  $\text{Na}^+\text{Tl}^-$ , where the polyanion or Zintl anion  $^{3-}\infty[\text{Tl}^-]$  forms a diamond framework.  $^{3-}\infty[\text{Tl}^-]$  can be thought of as a pseudoelement of group 14, recognizing that the diamond structure is a preferred structure type for this element. Laves listed all the intermetallic compounds whose structures were known in 1941 that obeyed the rules of valence under the heading 'Zintl phases', in recognition of Zintl's contribution to the study of these compounds.<sup>36</sup>

The ability of Zintl compounds to dissolve in coordinating solvents such as ammonia and ethylenediamine (en) is another property that sets these compounds apart from intermetallics. At the same time that much of this investigation of the solid state was occurring, several scientists, including Zintl, also were studying the solution chemistry of alkali metals in liquid ammonia with a variety of the heavy main group metals.<sup>4,5</sup> Electrochemical investigations indicated that there existed discrete anion clusters in these solutions and provided the first evidence for the so-called Zintl ions. The isolation of a solid derivative of a Zintl anion was first accomplished by Kummer and Diehl<sup>37</sup> with the compound,  $\text{Na}_4\text{Sn}_9 \cdot 7\text{en}$ . A large advance was made in this area by the use of crypt to sequester the cation and this allowed the isolation of a number of salts containing Zintl anions. Many of these solvated Zintl anions have been isolated and their structures determined. In addition, many have been used as precursors for the synthesis of new organometallic compounds, in the metallization of polymer substrates, and in the synthesis of novel magnetic colloids. The

classification of Zintl ions is normally limited to polyatomic anions of the metals of groups 14 and 15.<sup>4,38</sup>

### 3 STRUCTURE AND BONDING

#### 3.1 Solid-state Binary Compounds

Laves proposed that all intermetallic compounds that obeyed valence or the  $(8 - N)$  rule should be classified as Zintl compounds. These alkali and alkaline earth main group compounds typically crystallize in salt-like structures such as antifluorite, *anti*- $\text{Mn}_2\text{O}_3$ , and *anti*- $\text{La}_2\text{O}_3$ . For example, the compounds  $\text{A}^{\text{I}}_3\text{Pn}$  or  $\text{A}^{\text{II}}_3\text{Pn}_2$  can be formed; they consist of isolated A cations and Pn anions. The corresponding situation occurs for group 14 only with some of the alkaline earth cations. The term 'isolated' is used to describe atoms that do not form part of a polyatomic unit; the distance to another atom of the same type is too large to be considered a bond. Although these structures can be described as salt-like, the atoms have high coordination numbers typical of metals and the heavier groups 14 and 15 compounds are metallic. Many of the  $\text{A}^{\text{I}}_3\text{Pn}$  compounds have the hexagonal  $\text{Na}_3\text{As}$  (*anti*- $\text{LaF}_3$ ) structure in which equal numbers of Na and As form hexagonal nets (as in boron nitride) and the remaining Na atoms are arranged in layers on either side of these nets. Each As has five neighbors at the corners of a trigonal bipyramid and six other Na atoms in a trigonal prismatic arrangement, making the total coordination number of As to be 11. The Na atoms have two types of environment. The Na in the  $\text{NaAs}$  net has three As atoms and six Na atoms, whereas the Na in between the nets has four As and six Na nearest neighbors. Binary compounds with lithium have been excluded because in many cases they show unique behavior with respect to their structure and stoichiometries.<sup>33</sup> Table 1 gives some examples of binary Zintl compounds with salt-like structures.

The prototype Zintl compounds are those with the NaTl structure type. As more X-ray structure analyses were performed, the number of structure types that could be interpreted in such a manner increased. Klemm and Busmann<sup>39</sup> formalized this interpretation: the electropositive element transfers electrons to the electronegative element, which then uses these electrons to form an anion partial lattice that resembles the elemental lattice with the same number of valence electrons. The coordination in the anion partial lattice analogy conforms to the  $(8 - N)$  rule. In many of these structures, an analogy to the corresponding elemental lattices can be made. By obtaining one electron from an alkali metal, the group 13 elements can form a diamond lattice and are isostructural (and isoelectronic) with the corresponding group 14 elements. There has been a significant amount of research on the composition and properties of compounds that crystallize in the NaTl structure type.<sup>40</sup> These compounds show properties that are characteristic of covalently bonded

**Table 1** Structure types of binary solids with salt-like structures<sup>a</sup>

<sup>a</sup> —, compound unknown; ?, structure unknown.

compounds, although it has been shown that there are deviations in stoichiometry that give rise to metallic behavior. In addition to the example given above, further comparisons between polyatomic anions found in Zintl compounds and the isoelectronic elements can be made. For example, in the case of NaSi,<sup>41</sup> the Si is given a formal charge of  $-1$ . The structure contains isolated  $(\text{Si}_4)^{4-}$  tetrahedra that are isoelectronic and isostructural with  $\text{P}_4$ . Figure 1 shows a view of the unit cell. In addition, there are compounds whose anion lattices are not isosteric with elemental lattices having the same number of valence electrons. However, the coordination of the anion partial lattice conforms to the  $(8 - N)$  rule and thus can be described by normal valence rules. Table 2 gives a partial listing of some compounds obeying this rule.

**Figure 1** A view of the unit cell for NaSi showing the  $\text{Si}_4^{4-}$  tetrahedral**Figure 2** The structure of  $\text{Ba}_4\text{SiAs}_4$ 

### 3.2 Solid-state Ternary Compounds

The structure and bonding of ternary compounds can also be described within the Zintl concept. Some ternary Zintl compounds have structures that can be described as complex salts. For example,  $\text{Ba}_4\text{SiAs}_4$ ,<sup>42</sup> whose structure is shown in Figure 2, is composed of  $\text{SiAs}_4^{8-}$  tetrahedra whose charge is balanced by the alkaline earth cation. Such isolated tetrahedra are also formed with group 13 atoms in combination with group 14 or group 15 atoms. There are discrete  $\text{GeAs}_4^{8-}$ ,  $\text{GeP}_4^{8-}$ , and  $\text{SiP}_4^{8-}$  tetrahedra in this structure type whose charges are balanced by the alkaline earth cations. The term orthophosphido- or orthoarsenidosilicates or -germanates has been used to describe these anions because they are isoelectronic with the ordinary silicate ( $\text{SiO}_4^{4-}$ ), with the  $\text{O}^{2-}$  ions being replaced by  $\text{As}^{3-}$  or  $\text{P}^{3-}$  ions.<sup>27</sup> According to the  $(8 - N)$  rule, Ge or Si is given a formal charge of zero and the As or P is assigned a formal charge of  $-2$ , giving rise to the overall charge of  $-8$  on the polyatomic unit. The compound  $\text{A}_2\text{SiAs}_2$  ( $\text{A}^I = \text{K}, \text{Rb}, \text{Cs}$ )<sup>43–45</sup> can be prepared and is composed of anionic chains of  $[\text{SiAs}_4/2]^{2-}$  (edge-sharing tetrahedral) (Figure 3). The anionic lattice is isoelectronic and isostructural with  $\text{SiS}_2$ .

Synthesis with cations of different sizes provides two new structures in the system  $\text{A}^{\text{II}}\text{—Si—As}$ :  $\text{Sr}_3\text{Si}_2\text{As}_4$  and  $\text{Ca}_3\text{Si}_2\text{As}_4$ , Figures 4 and 5.<sup>46,47</sup> These two structures contain  $\text{Si}_2\text{As}_6$  units that are linked in different ways. The  $\text{Si}_2\text{As}_6$  anions found in  $\text{Sr}_3\text{Si}_2\text{As}_4$  are connected by a common edge as shown in Figure 4 and can be described by the notation  $[\text{SiAs}_2/2]^{6-}$ . In the case of  $\text{Ca}_3\text{Si}_2\text{As}_4$ , one of the Si has all three of the As bonded to another  $\text{Si}_2\text{As}_4$  unit, whereas the Si in the other half has only one As bonded to another  $\text{Si}_2\text{As}_4$  unit (Figure 5). The anionic unit can be described as consisting of  $[\text{As}_2\text{As}_1/2\text{SiSiAs}_3/2]^{6-}$  chains. Many of these ternary compounds are classified as Zintl compounds. However, few transport properties have

**Table 2** Examples of binary compounds obeying the Zintl concept

| N | Compound          | Formal charge | Coordination | Structure of anion lattice                              | Structure type    |
|---|-------------------|---------------|--------------|---------------------------------------------------------|-------------------|
| 4 | LiAl              | −1            | 4            | Diamond                                                 | NaTl              |
|   | LiIn              |               |              |                                                         | NaTl              |
|   | NaIn              |               |              |                                                         | NaTl              |

**Figure 3** A view of the structure of  $A_{12}SiAs_2$  showing the  ${}^1_{\infty}[SiAs_{4/2}]^{2-}$  chains**Figure 4** A view of the structure of  $Sr_3Si_2As_4$  showing the  ${}^1_{\infty}[(SiAsAs_{2/2})_2]^{6-}$  chains

been measured, because their structures can be interpreted according to the  $(8 - N)$  rule. Table 3 gives a partial listing of ternary Zintl phases with complex anions.<sup>25–27,48,49</sup> In addition, exploring the Zintl boundary has led to the discovery of novel cluster solid-state compounds.<sup>5,50</sup>

### 3.3 Transition Metal Zintl Compounds

The Zintl concept has been extended to include transition metal compounds, with some success.<sup>1,18,28,31,32,51,52</sup> Although many main group metal Zintl compounds are known,<sup>25–27,33</sup> there are relatively few examples of isostructural transition

**Figure 5** A view of the structure of  $\text{Ca}_3\text{Si}_2\text{As}_4$  showing the  $1_\infty[(\text{As}_2\text{As}_{1/2}\text{SiSiAs}_{3/2})^{6-}]$  chains

**Table 3** Examples of ternary compounds obeying the Zintl concept

| Compound                            | Structure of anion lattice                                               | Structure type                      |

| $\text{Sr}_5\text{In}_2\text{Sb}_6$ |                                                                          |                                     |
| $\text{Ca}_{14}\text{AlSb}_{11}$    | $\text{AlSb}_4^{9-} + \text{Sb}_3^{7-} + \text{isolated Sb}^{3-}$ anions | $\text{Ca}_{14}\text{AlSb}_{11}$    |
| $\text{Sr}_{14}\text{GaAs}_{11}$    |                                                                          |                                     |
| $\text{Ca}_{11}\text{InSb}_9$       | $\text{InSb}_4^{9-} + \text{Sb}_2^{4-} + \text{isolated Sb}^{3-}$ anions | $\text{Ca}_{11}\text{InSb}_9$       |
| $\text{Ca}_{11}\text{AlSb}_9$       |                                                                          |                                     |

metal analogs. Some transition metal sulfides have been described by the Zintl rules.<sup>28</sup> Binary and ternary transition metal complexes with metals having filled d orbitals can also be described according to the Zintl concept, although inclusion of the d orbitals complicates the bonding description.<sup>28</sup> The Zintl concept has also been used to explain the structure and properties of ternary transition metal pnictides crystallizing in the  $\text{ThCr}_2\text{Si}_2$  structure type.<sup>51,52</sup> Two structure types that appear to be amenable to having a transition metal replacing the main group metalloid are the  $\text{A}^{\text{II}}_{14}\text{MPn}_{11}$  ( $\text{M} = \text{Al}$ ,<sup>53,54</sup>  $\text{Ga}$ ,<sup>55,56</sup>  $\text{In}$ ,<sup>57</sup>  $\text{Mn}$ ,<sup>30–32</sup>  $\text{Zn}$ ,<sup>58</sup>  $\text{Nb}$ ,<sup>59</sup> and  $\text{Pn} = \text{P}$ ,  $\text{As}$ ,  $\text{Sb}$ ,

$\text{Bi}$ ) compounds and the  $\text{A}^{\text{I}}_5\text{MPn}_3$  ( $\text{M} = \text{Si}$ ,  $\text{Ge}$ ,<sup>60</sup>  $\text{Sn}$ ,  $\text{Hf}$ <sup>61</sup>) compounds. There have also been a number of new transition metal Zintl phases prepared which have no structure type equivalent to the main group elements, but appear to be valence precise and semiconducting.<sup>62–67</sup>

The structure and bonding in the  $\text{A}^{\text{I}}_5\text{HfPn}_3$  can be easily understood in terms of the Zintl rules, since the Hf is formally a +4 ion. In this structure, two  $\text{HfAs}_4$  tetrahedra are connected by a common edge to form  $(\text{Hf}_2\text{As}_6)^{10-}$  anions. The structure and bonding in the  $\text{A}_{14}\text{MPn}_{11}$  series of compounds is more complicated. In the framework of the Zintl rules, the structure of these compounds,  $\text{A}_{14}\text{MPn}_{11}$  can be understood as consisting of 14  $\text{A}^{2+}$  cations, four  $\text{Pn}^{3-}$  anions, a  $\text{MPn}_4^{9-}$  tetrahedron, and a linear  $\text{Pn}_3^{7-}$  unit. Figure 6 shows a perspective view of the unit cell. The  $\text{Pn}_3^{7-}$  unit is well described as a three-center-two-electron bond and is isoelectronic with  $\text{X}_3^-$  ( $\text{X} = \text{halogen}$ )<sup>68</sup> (see *Hypervalent Compounds*). These compounds are isostructural with the main group Zintl compounds, and so the transition metal Mn has been proposed to be  $\text{Mn}^{3+}$ .<sup>30–32</sup> A more recent understanding of the bonding has recently lead to a different picture with the Mn better considered to be formally  $\text{Mn}^{2+}$ .<sup>69,70</sup> In this view, the charge counting of the tetrahedron can be explicitly stated as  $[\text{Mn}^{2+}(\text{Sb}_4)^{11-}]$  rather than  $[\text{Mn}^{3+}(\text{Sb}_4)^{12-}]$ . In either description, the paramagnetic temperature-dependent magnetic susceptibility data is consistent with four unpaired electrons. However, this electronic structure leads to unusual magnetic and electronic transport properties (see *Magnetism of Transition Metal Ions*).<sup>32</sup>

Recent publications on other transition metal Zintl phases<sup>62–67</sup> suggest that this is a rich area for study with applications for magnetic and electronic devices.

**Figure 6** A perspective view of the structure of  $\text{A}_{14}\text{MPn}_{11}$

## 3.3.1 Zintl Ions

This subtopic of Zintl compounds relates to those homo- and heteropolyanions that have been isolated and characterized. Although clusters containing the heavier group 16 chalcogenides, such as Se and Te, are sometimes considered to be Zintl anions, those compounds are not considered here. Chalcogenides have extensive cluster chemistry and are traditional anions. It has been known for some time that sodium and lead or their alloys dissolve in liquid ammonia to yield an intensely colored green solute.<sup>71</sup> Electrochemical investigations of these solutions led to the hypothesis that the Pb exists as  $\text{Pb}_9^{4-}$  in solution.<sup>72</sup> Zintl and coworkers extensively studied these types of solutions and were able to identify  $\text{Sn}_9^{4-}$ ,  $\text{Pb}_7^{4-}$ ,  $\text{Pb}_9^{4-}$ ,  $\text{Sb}_5^{3-}$ ,  $\text{Sb}_7^{3-}$ ,  $\text{Bi}_3^{3-}$ ,  $\text{Bi}_5^{3-}$ , and  $\text{Bi}_7^{3-}$ .<sup>73</sup> However, structural studies were not possible owing to decomposition of the solids isolated by solvent evaporation. There was little work in this area again until 1970, when several Zintl anions were isolated from ethylenediamine (en) solutions.<sup>4,38</sup> A structural study of one of these compounds,  $\text{Na}_4\text{Sn}_9 \cdot 7\text{en}$ , showed a  $\text{Sb}_9$  polyhedron.<sup>37</sup> Two other compounds,  $\text{Na}_3\text{Sb}_7 \cdot 4\text{en}$  and  $\text{Na}_4\text{Ge}_9 \cdot 5\text{en}$ , were prepared by this method.<sup>74</sup> A significant number of Zintl anions were discovered by the use of a *Macrocyclic*, crypt, to stabilize the polyatomic anions, which allowed for their isolations and structural characterization. In addition, heteropolyatomic anions are also possible and have been synthesized and characterized. Table 4 gives some examples of Zintl anions that have been structurally characterized.

## 3.3.2 Reactivity

Incorporation of transition metals into the Zintl anions described above has been somewhat successful, although in many cases, the emphasis has been on the solution chemistry of the metal chalcogenides. The heavier group 14/15 anion clusters, such as  $\text{Sn}_9^{4-}$ ,  $\text{Sb}_7^{3-}$ , and  $\text{As}_{11}^{3-}$ , have received much less attention but have proved to be equally interesting.<sup>38,50</sup> More recently, there has been renewed interest

in exploring Zintl ions prepared from dissolving Zintl phases with an aim towards understanding cluster growth and the solution chemistry of these phases.<sup>10,11,38,75–77</sup>

The reactivities of the binary Zintl compounds have been explored for the synthesis of new compounds.<sup>78</sup> There have been new compounds prepared by the reaction of Zintl phases with a metal or metal carbonyl to produce new compounds such as  $[\text{Rb}(\text{NbAs}_8)]^{2-}$ .<sup>6</sup> The compounds contains chains of alternating  $\text{Rb}^+$  cations and  $[\text{NbAs}_8]^{3-}$  units that each consist of a monocyclic crown shaped polyanion  $\text{As}_8^{8-}$  with a  $\text{Nb}^V$  ion in the center. More recently, the series of compounds with  $\text{ME}_8^{n-}$  anions ( $\text{M} = \text{Cr}, \text{Mo}$ ;  $\text{E} = \text{As}, \text{Sb}$ ) have been crystallized and their properties explored.<sup>79</sup>  $\text{Sn}_9\text{Cr}(\text{CO})_3^{4-}$  was prepared by reacting  $\text{Cr}(\text{CO})_3(\text{Mes})$  with a deep red en extract of  $\text{K}_4\text{Sn}_9$ . The crystals were isolated by the use of the crypt complexing agent to give  $[\text{K}(\text{crypt})_4][\text{Sn}_9\text{Cr}(\text{CO})_3]^{4-}$ .<sup>8</sup> The structure consists of a *nido*- $\text{Sn}_9^{3-}$  cluster (isoelectronic and isostructural with  $\text{B}_{10}\text{H}_{10}^{2-}$ ) which is bonded in an  $\eta^4$  fashion to the  $\text{Cr}(\text{CO})_3$  fragment.  $\text{As}_7\text{Cr}(\text{CO})_3^{3-}$  can be prepared in an analogous manner as described above from a Zintl phase dissolved in en and a metal carbonyl.<sup>9</sup> The structure consists of an open  $\text{As}_7$  cage that is bound in an  $\eta^4$  fashion to the  $\text{Cr}(\text{CO})_3$  fragment.

Reactions of metal carbonyls with Zintl phases do not always yield the desired result. An example is the reaction of  $\text{KSi}$  with the metal carbonyls  $\text{M}(\text{CO})_6$  ( $\text{M} = \text{Cr}, \text{Mo}, \text{W}$ ) and the chromium complex  $\text{Cr}(\text{CO})_5\text{NMe}_3$ .<sup>80</sup> Instead of forming a structure with a  $\text{Si}_4$  anion,  $\text{KSi}$  reduces these transition metal compounds to form the anions,  $[\text{M}_2(\text{CO})_{10}]^{2-}$ . In addition, certain organometallic transition metal clusters have been synthesized that contain Zintl anions coordinated to the metal,<sup>81–84</sup> but Zintl compounds are not used as the reagents.

The salt-like description of bonding between the cations and polyatomic anions of Zintl compounds adequately accounts for their solubility in polar solvents. As mentioned above, a large number of binary Zintl compounds will dissolve in ammonia or amine solvents. Some Zintl phases will even dissolve in methanol (e.g.  $\text{K}_4\text{SnTe}_4$ ).<sup>15</sup> These Zintl anions have been studied in solution and can react with transition metal cations to give new intermetallic phases. The reaction consists of electron transfer from the Zintl polyanion to the transition metal cations, resulting in the rapid precipitation of the neutral solid product. The intermetallic solids formed by this route are often amorphous and metastable. Using this simple metathesis reaction with, for example,  $\text{K}_4\text{SnTe}_4$ , a series of ternary transition metal chalcogenides of the formula  $\text{M}_2\text{SnTe}_4$  ( $\text{M} = \text{Cr}, \text{Mn}, \text{Fe}, \text{Co}, \text{Ni}$ , and  $\text{Cu}$ ) have been synthesized and characterized.<sup>15,17</sup> In addition, the compounds  $\text{M}_5(\text{InTe}_4)_2$  ( $\text{M} = \text{Cr}, \text{Mn}, \text{Fe}, \text{Co}$ , and  $\text{Ni}$ ) have been synthesized and characterized.<sup>85–87</sup> These materials exhibit remarkable properties, including a spin glass transition at temperature ranging from 5 to 18 K.

Zintl ion solutions have been explored for the metallization of polymers.<sup>14</sup> Oxidizing polymers such as polyimide can be topochemically metallized by reaction with Zintl ion solutions.

Table 4 Examples of Zintl anions

| Anion                         | Symmetry   | Isoelectronic analog                                                                |

In addition, the reactivity of Zintl ion solutions with layered materials have been reported. Solutions of  $K_4Sn_9$  in en reduce graphite and  $HfTe$ ; the potassium is intercalated into the structure and tin metal is deposited on the edges of the layered substrate.<sup>13</sup>

More recently Zintl phases have been used to prepare novel semiconducting phases such as nanocrystals.<sup>7,88-90</sup> Group IV nanoparticles have been prepared either by metathesis route or an oxidation of a binary Zintl phase.

#### 4 CHARACTERIZATION

The results of X-ray crystal-structure determinations have assumed great significance in discussions of the bonding in these phases. Relatively speaking, this is the field with the greatest amount of experimental material. In addition, in recent years the requirement of additional characterization by most Journals has resulted in more property measurements and theoretical calculations on Zintl phases published.

Theoretical calculations on compounds crystallizing in the NaTl structure type have been performed and their properties reviewed.<sup>40</sup> In addition to the crystal structure, the thermodynamic behavior, electrical conductivity, magnetic susceptibility, nuclear magnetic resonance (NMR) data, elastic constants, and optical properties have been studied. Based upon experimental data, the bonding in Zintl phases is considered to be a mixture of covalent, ionic, and metallic contributions. In many cases, the transport properties indicated metallic behavior arising from deviations from ideal stoichiometry. However, the thermal and elastic behavior of these phases indicates strong covalent bonding. Most theoretical studies have focused on compounds in which the Zintl concept does not appear to hold, such as  $Ba_7Ga_4Sb_9$ <sup>91</sup> or  $A_{14}MPn_{11}$ .<sup>68,69</sup> Theoretical calculations have also been performed on Zintl anions such as  $X_2Y_2$  type clusters,<sup>92,93</sup> as well as the more classic structures that are considered to be Zintl ions.<sup>4,38</sup>

A few IR and Raman spectroscopic investigations on Zintl ions have been reported. The assignment of the observed frequencies is determined by normal coordinate analysis and force constants for such compounds as  $Cs_6M_2Pn_4$  ( $M = Al, Ga; Pn = P, As$ ),<sup>94</sup>  $Cs_6MPn_3$  ( $M = In, Al; Pn = As, Sb$ ),<sup>95</sup> and  $M_3Pn_{11}$  ( $M = Na, K, Rb, Cs; Pn = P, As$ ).<sup>96</sup> Some properties of the homoatomic nine-atom Zintl ions of group 14 (Si–Pb) have been reviewed.<sup>38</sup>

Nearly all information on the solution chemistry of the Zintl ions has come from NMR studies.<sup>97-101</sup> The majority of these were carried out in en without the addition of crypt. Clusters that have been identified by  $^{119}Sn$ ,  $^{205}Tl$ , or  $^{207}Pb$  NMR include  $Sn_{9-x}Pb_x^{4-}$  ( $x = 0-9$ ),  $Sn_{9-x}Ge_x^{4-}$  ( $x = 0-9$ ),  $Sn_8Tl^{5-}$ ,  $Sn_4^{2-}$ ,  $SnTe_4^{4-}$ ,  $Sn_{8-x}Pb_xTl_n^{n-}$  ( $x = 1-4, n$  probably 5), and  $Sn_2Bi_2^{2-}$ .

## Abbreviations

Ar'O = 2,6-di-*t*-butylphenoxide; acac = acetylacetonate; bppy = 4-(1-butylpentyl)pyridine; cup = cupferron; dippe = 1,2-bis(diisopropylphosphino)ethane; dppe = 1,2-bis(diphenylphosphino)ethane; fcc = face-centered cubic; <sup>t</sup>R = CH(CF<sub>3</sub>)<sub>2</sub>; hcp = hexagonal close-packed; hexone = methyl isobutyl ketone; OEP = octaethylporphyrinogen; phen = phenanthroline; py' = 4-pyrrolidinopyridine; tritox = (*t*-Bu)<sub>3</sub>CO<sup>-</sup>; tbp = Bu<sub>3</sub>PO<sub>4</sub>; TPP = tetraphenyl-porphyrinogen; trmpe = tris(dimethylphosphinomethyl)ethane.

## 1 INTRODUCTION

Zirconium (atomic number 40) and hafnium (atomic number 72) are members of group 4 of the *periodic table* (see *Periodic Table*), below titanium (atomic number 22) and above Rutherfordium, (element 104). Zirconium (named from the Arabic *zargun*, meaning gold-colored) was discovered in 1789 by the German chemist Martin Heinrich Klaproth (1743–1817), who prepared zirconium oxide from the mineral zircon, ZrSiO<sub>4</sub>. Gems that contain zirconium were known in the ancient world and were known by such names as

hyacinth, jacinth, jargon, and zircon. It was such a specimen of zircon from Ceylon (Sri Lanka) that Klaproth heated with alkali to produce a new oxide, which he called *zirconia*. The Swedish chemist Jöns Jacob Berzelius isolated zirconium in the free state by reduction of potassium hexafluorozirconate (K<sub>2</sub>ZrF<sub>6</sub>) with potassium in a sealed iron tube to obtain a black powder.

Dimitri Mendeleev predicted the existence and the main properties of the 72nd element in 1870, and George Urbain in 1911 mistakenly thought he had discovered it, calling it celtium. Henry Moseley deduced the presence of element 72 (among the other undiscovered elements 43, 61, and 75) from X-ray spectra, but was misled thinking that it was the recently announced celtium. Celtium was discredited, but in 1923 Dirk Coster of the Netherlands and George Charles de Hevesy of Hungary used Moseley's method of X-ray analysis on a sample of Norwegian zircon and observed the spectrum for the element, which proved to be hafnium. It was named after Hafnia, the Latin name for Copenhagen where the discovery was made. Pure metallic hafnium was first obtained in 1925 by decomposing hafnium tetraiodide (HfI<sub>4</sub>) over a hot tungsten wire.<sup>1</sup>

In most of their compounds, zirconium and hafnium exist in the oxidation state IV (see *Oxidation Number*). Compared with titanium, their M<sup>III</sup> chemistry is limited,<sup>2</sup> but they show much greater ability to form M–M bonds in oxidation states ≤ III (for example, in dimers, layered compounds, and M<sub>6</sub>Cl<sub>12</sub> clusters). The basicities of the group 4 elements increase in the order Ti < Zr < Hf. Therefore the MX<sub>4</sub> compounds with d<sup>0</sup> configuration (see *d<sup>n</sup> Configuration*) readily produce high CN neutral or anionic coordination complexes (see *Coordination Complexes*) with Lewis bases. Zirconium and hafnium compounds are rather hard Lewis acids and yield stable complexes with hard bases, such as O- and N-donor ligands (see *Ligand*). The coordination and organometallic complexes of zirconium and to a lesser extent, hafnium, have found use in both hetero- and homogeneous catalysis. In aqueous solutions, Zr and Hf ions are extensively hydrolyzed, and their cations form polynuclear species. In contrast to niobium and tantalum, their neighbors in the periodic table, and titanium, their lighter congener, zirconium and hafnium do not form M=O<sup>2+</sup> species (see *Periodic Table: Trends in the Properties of the Elements*). The chemistry of zirconium and hafnium is characterized by their remarkable resemblance, which is due to their almost identical atomic sizes owing to the lanthanide contraction and their analogous electronic structures.<sup>3,4</sup>

The development of nuclear power opened a new chapter in the inorganic chemistry of these two elements. They show useful but diametrically opposite abilities to transmit thermal neutrons, a fact that stimulated the development of methods for their isolation, careful separation, and metal analysis (see *Metal Analysis*).

## 2 PROPERTIES OF THE ELEMENTS

### 2.1 Physical Properties

Table 1 summarizes some of the properties of zirconium and hafnium. Each element has several naturally occurring isotopes. The least abundant of these are  $^{96}\text{Zr}$  (2.76% natural abundance) and  $^{174}\text{Hf}$  (0.162% n. a.), which are radioactive with half-lives of  $3.6 \times 10^{17}$  y and  $2.0 \times 10^{15}$  y, respectively. The man-made isotopes  $^{95}\text{Zr}$  ( $t_{1/2} = 65.3$  d),  $^{175}\text{Hf}$  ( $t_{1/2} = 70$  d), and  $^{181}\text{Hf}$  ( $t_{1/2} = 70$  d) are used as tracers in scientific research.

In appearance, the metals are lustrous, silvery, and ductile and have high melting points. Their structures are typically hcp, which transform to bcc at high temperatures (870 °C for Zr and 1760 °C for Hf). Owing to the lanthanide contraction (see *Lanthanide Contraction*), the metallic and ionic radii of the two elements are almost identical. As a result, the properties of the metals are very similar.

### 2.2 Chemical Properties

Zirconium and hafnium possess nearly identical chemistry. No other pair of congeners has chemical properties so similar to each other. This is mostly a result of the metals possessing nearly identical atomic and ionic radii (1.45 and 1.44 Å for Zr and Hf, and 0.86 and 0.85 Å for  $\text{Zr}^{4+}$  and  $\text{Hf}^{4+}$ ) as a result of the lanthanide contraction. They are relatively electropositive, but less so than the group 3 metals. The metals themselves

are highly pyrophoric when finely divided. However, in the bulk form at room temperature they are resistant to corrosion, which is due to the formation of a dense protective oxide film. At high temperature, they react directly with most nonmetals, especially oxygen, hydrogen, and the halogens. For example, the metals burn in oxygen and chlorine gas to yield  $\text{MO}_2$  and  $\text{MCl}_4$ , respectively. Mineral acids (with the exception of hydrofluoric acid) have little effect on the metals unless hot. Oxidizing agents such as nitric acid frequently reduce the activity of the metals by stabilizing the adherent oxide film. Aqueous alkalis have no effect, even at elevated temperatures.

## 3 NATURAL ABUNDANCE AND PRODUCTION

### 3.1 Natural Abundance

Zirconium comprises 0.016% (162 ppm) of the Earth's crust and, as a transition element, is only less abundant than Fe, Ti, and Mn. Hafnium is much less abundant at 2.8 ppm, but is still comparable in quantity to Cs and Br. The most important minerals of zirconium are zircon ( $\text{ZrSiO}_4$ ), which is mostly mined in Australia, South Africa, the USA, and Sri Lanka, and baddeleyite ( $\text{ZrO}_2$ ), found mostly in Brazil. The estimated reserves exceed a billion tonnes. Australia and South Africa account for about 80% of zircon mining. All zirconium minerals are contaminated by small quantities of hafnium (0.5–2% of Zr content), but in a few (such as alvite,  $\text{MSiO}_4 \cdot x\text{H}_2\text{O}$ ,  $\text{M} = \text{Hf, Zr, Th}$ ) the content of Hf is comparable with that of Zr. The above-mentioned similarities in the chemical behavior of these metals explain their close association in Nature and the similarity of their isolation procedures.

### 3.2 Industrial Isolation and Production

There are three industrial routes used for the extraction of zirconium and hafnium from ores: (1) caking of zircon with  $\text{K}_2\text{SiF}_6$ , alkaline extraction of the cake, separation of  $\text{K}_2\text{HfF}_6$  from  $\text{K}_2\text{ZrF}_6$  by fractional crystallization, and reduction of the complex fluorides to the metal; (2) chlorination of zircon in the presence of coke, purification of  $\text{MCl}_4$  (for example, by distillation of adducts with  $\text{POCl}_3$ ), and their reduction by metallothermy; (3) caking of zircon with lime, soda, or  $\text{NaOH}$ , acid extraction of the cake, extractive separation by hexone as the thiocyanates or by tributyl phosphate as the nitrates, and precipitation of the tetrafluorides by HF and their reduction to the metal.

The most important commercial methods of production of metallic zirconium and hafnium are based on furnace reduction, either of  $\text{MCl}_4$  with magnesium or a Na–Mg mixture (the Kroll process), yielding a metal sponge, or of metal fluorides with Ca at 2000 °C to give an ingot. The

**Table 1** The main properties of zirconium and hafnium

| Property                                                  | Zirconium             | Hafnium                      |

elimination of oxygen and nitrogen impurities is achieved by the van Arkel–de Boer process, which involves the heating of a crude sponge metal *in vacuo* with iodine to give volatile  $MI_4$ , and the decomposition of the iodide at a filament heated above 1300 °C. The annual world production of zircon exceeds 900 000 tonnes and that of zirconium metal is about 7000 tonnes. Industrial production of hafnium metal is about 50 tonnes a year.

### 3.3 Separation

Despite zirconium and hafnium being among the most difficult elements to separate, some highly effective methods have been developed to purify the metals.<sup>5</sup> The most effective method is a liquid extraction. Fractional crystallization of the fluorides  $K_2HfF_6$  and  $K_2ZrF_6$  (mentioned above) is used now only for the concentration of hafnium. The solubilities of  $K_2HfF_6$  in water and  $KHfF_5$  in 0.7 M HF are about 1.5 and 2.2 times as much as those of  $K_2ZrF_6$  and  $KZrF_5$  in the respective solvent thereby allowing the accumulation of Hf in solution. The different solubilities of the zirconium and hafnium phosphates in strong acid media, of the cupferronates (see *Cupferron*) in HF solutions, and of their hydroxides allow their separation by fractional precipitation.

Separation of the tetrahalides can be achieved from their solutions in molten salts ( $K_2ZrF_6$ , NaCl,  $SnCl_2$ ) or under pressure (10–70 atm). However, distillation of the adducts of the tetrachlorides with  $POCl_3$  is a more convenient route. Borohydrides and alkoxides of Zr and Hf are more volatile, but their complicated syntheses and high air-sensitivity limit their usefulness.

There are a few differences in the chemical behavior of zirconium and hafnium that can be exploited for their separation. The equilibrium constant of the reaction shown in equation (1) for Zr is greater than 10 orders of magnitude larger than for Hf. Therefore, reaction of a mixture of  $MCl_4$  vapors with  $O_2$  and  $Cl_2$  at 500–900 °C selectively oxidizes Zr to  $ZrO_2$  and leaves  $HfCl_4$ . On heating a mixture of  $MCl_4$  with Zr or Al metal *in vacuo* at 400–450 °C, most of the  $ZrCl_4$  is reduced to nonvolatile  $ZrCl_3$  while  $HfCl_4$  is left unchanged and can be distilled from the reaction mixture. Electrolysis of  $K_2MF_6$  in molten NaCl–KCl mixture at 650–700 °C first gives  $MCl_2$  but ultimately yields mainly metallic Zr.

Ion exchange and chromatography are used most often in analytical chemistry, due to the low concentration of the final solutions. Zr and Hf can be separated in anionic forms in sulfuric acid or concentrated HCl or HF with anion exchange resins like Dowex 2, or in cationic forms in diluted acids with cation exchange resins like Dowex 50.

Liquid extraction methods are based on the differential distribution coefficients of Zr and Hf between aqueous and organic phases. For example, hexone and other ketones (such

as cyclohexanone) are used to extract hafnium into the organic phase from acid rhodanide solutions while tributyl phosphate (tbp) extracts zirconium into the organic phase from nitric acid or its mixture with HCl as complexes with one or two tbp ligands. The composition of the extracted species depends on the composition and pH of the aqueous phase. In 5 M HCl/ $HNO_3$  (1:1), the composition of the extracted complex is  $ZrOCl(NO_3) \cdot n(tbp)$ , while in concentrated nitric acid it is  $Zr(NO_3)_4 \cdot n(tbp)$ . It is assumed that hafnium is extracted as  $Hf(NO_3)_4 \cdot 2(tbp) \cdot nHNO_3$ . From chloric acid solutions the metals are effectively extracted with fluorinated diketones (see *Diketones*), such as thenoyltrifluoroacetone (tta).

### 3.4 Uses

Zirconium metal has a very high corrosion resistance except toward fluoride ions, *aqua regia*, concentrated sulfuric acid, wet chlorine, and iron(III) and copper(II) chlorides. It has found use alongside stainless steel, titanium, and tantalum in the production of chemical apparatus. Zirconia has a very high melting point (above 2500 °C) and is used to make heat-resistant crucibles, ceramics, and abrasives. The generally low toxicity (except to individual allergic reactivity) has given zirconia use in cosmetics, antiperspirants (as zirconium hydroxychloride in roll-on deodorants), and food packaging.

In the 1940s, zirconium and hafnium metals were brought to prominence by their use in the nuclear industry in nuclear reactors and submarines. Zirconium and hafnium differ completely in their ability to transmit thermal neutrons. Zirconium is practically transparent to these particles (with a cross section for thermal neutron capture of 0.18 barns) whereas hafnium is a powerful absorber (105 barns). Both metals, therefore, are used in the nuclear industry: zirconium is used as a cladding for the uranium dioxide fuel rods of water-cooled nuclear reactors, while hafnium is used as a material for reactor control rods (for example, in nuclear submarines) and for protective screens in reactors. The nuclear industry consumes about 90% of the total world zirconium and hafnium output. The corrosion resistance of pure zirconium is insufficient for nuclear technology, so a series of alloys containing Sn, Fe, Cr, and Ni ('Zircalloys', the cross section of which is only 0.22 barns) have been developed.<sup>6</sup> Zirconium is also used as a getter, as an electrode material, and as a component of a variety of alloys including superconducting niobium-based alloys that retain their superconductivity (see *Superconductivity*) in strong magnetic fields. Zirconium–zinc alloys become magnetic at temperatures below 35 K. The addition of 0.1% Zr to steel increases its hardness and toughness and the element is therefore used in the production of steel armor plate. Zirconium alloys exhibit catalytic activity for ammonia synthesis and conversion of  $SO_2$  to  $SO_3$  (see *Catalysis*).

The uses of zirconium and hafnium compounds based on their thermal and corrosion stability are described in related sections (see below). The most dramatic use of zirconium

(in the form of zirconia) is in ultrastrong ceramics. This was developed from the need for tank engines that would tolerate very high temperatures without the need of lubrication or a cooling system. Consequently, these tough, heat-resistant ceramics that are sharper than toughened steel make excellent industrial high-speed cutting tools. They have also found use in consumer goods such as knives, scissors, and golf irons, in addition to medical use as bioceramics in prosthetic joint replacement.

#### 4 OXIDATION STATES, COORDINATION NUMBERS, AND STEREOCHEMISTRY

The chemistry of hafnium has not been studied to nearly the same extent as zirconium, but its behavior very closely resembles that of the lighter metal. The most important oxidation state of these metals is almost exclusively the group oxidation state of IV. Lower oxidation states are only sparsely represented in contrast to titanium for which oxidation state III is also characteristic (*see Titanium: Inorganic & Coordination Chemistry*). The  $M^{III}$  state has no aqueous chemistry, since it readily reduces water. Nevertheless, lower oxidation states of zirconium and hafnium have been reported in a few inorganic solids (III, II, I) and recently in organometallic and coordination compounds in nonaqueous solutions (III, II, 0,  $-II$ ). Ligands such as cyclopentadienyl (*see Cyclopentadienyl*) or dienes (*see Diene Complexes*) effectively stabilize lower oxidation states of Zr and Hf, and a large number of bis- and monocyclopentadienyl  $M^{III}$  and  $M^{II}$  complexes have been reported (*see Zirconium & Hafnium: Organometallic Chemistry*).

The standard electrode potentials of  $Zr/Zr^{4+}$  and  $Hf/Hf^{4+}$  couples in aqueous solution are  $-1.529$  and  $-1.70$  V versus SHE, where SHE is the standard hydrogen electrode (*see Redox Properties & Processes*). Hafnium has the most negative reduction potential among the transition metals (*see Transition Metals*). In alkaline solution, the standard electrode potentials (equation 2) shift to the anodic region ( $-2.36$  and  $-2.50$  V, respectively), becoming (for Hf) more negative than those of the actinides. The standard electrode potentials, including intermediate oxidation states, measured in a molten NaCl–KCl mixture at 1000 K are  $-1.338$  V ( $Zr^{2+}/Zr^0$ ),  $-0.954$  V ( $Zr^{3+}/Zr^{2+}$ ), and  $-0.377$  V ( $Zr^{4+}/Zr^{3+}$ ) vs. Ag/AgCl, while the potentials of the  $Zr^{4+}/Zr^0$  and  $Hf^{4+}/Hf^0$  couples are  $-1.002$  and  $-1.185$  V respectively.

Coordination numbers (CN) of zirconium and hafnium range from 4 to 12, but because of the large values of their ionic and covalent radii (*see Covalent Radii*) (Table 1), their complexes typically have CNs of 6–8 (*see Coordination Numbers & Geometries*). They have a varied stereochemistry

(*see Stereochemistry*), as a result of the spherical symmetry of their  $d^0$  configuration and the consequent absence of ligand field effects. Typical coordination polyhedra are listed in Table 2. Thus, for CN 8, the coordination polyhedra most often observed are the dodecahedron (*see Dodecahedral*) and the square antiprism (*see Square Antiprism*). Chelating ligands (*see Chelate Effect*) forming five-membered metallacycles (such as  $C_2O_4^{2-}$ ) tend to give a dodecahedral structure, while the preferred geometry for ligands that form six-membered metallacycles (such as acac) is the square antiprism.<sup>7</sup> Analogously, replacing the rather small bidentate ligand  $NO_3^-$  by the larger  $IO_3^-$  causes a change from a dodecahedral arrangement of the metal atom to a square antiprismatic one. Maximum CN values of 10 and 12 are noted for the very small hydride ligand, typically in the form of borohydride,  $BH_4^-$ , complexes (*see Hydride Complexes of the Transition Metals*). Coordination numbers of 8 and 7 are typical for small ligands like  $F^-$ ,  $O^{2-}$ , or  $OH^-$ , while in most chloride and alkoxide complexes the metal atom has an octahedral arrangement (*see Structure & Property Maps for Inorganic Solids*). An increase of substituent bulk in a second coordination sphere reduces the CN to 5 or even 4 (*see Coordinative Saturation & Unsaturation*).

It should be noted that zirconium and hafnium usually form electron deficient complexes (*see Electron Deficient Compound*), which do not obey the Effective Atomic Number Rule (EAN rule) (*see Effective Atomic Number Rule*) and have a maximum of only 16 electrons. Monomers  $MX_4$  with monodentate ligands are rather strong Lewis acids and readily yield adducts with two, three, or four donor ligands. In  $MX_4$  monomers with  $\pi$ -donor ligands X (*see  $\pi$ -Base*), there is a noticeable shortening of the M–X distances in comparison with the sum of the covalent radii ( $0.26$  Å for  $X = F$ ;  $0.15$  Å for  $X = Cl, NMe_2$ ), thus pointing to some multiple bond character in these compounds.

Structures of di- and monovalent zirconium and hafnium compounds contain octahedra, chains, or layers of metal atoms with metal–metal bonds. It is this that differentiates these compounds from those of  $M^{III}$  ( $MX_3$  or molecular  $M_2X_6L_4$  complexes) with isolated M–M bonds. A recent reinvestigation of the  $ZrI_3$  structure showed two distinct Zr–Zr distances ( $3.507$  and  $3.172$  Å); the latter is typical for a Zr–Zr bond (*see Bond Length*).

## 5 BINARY AND MIXED COMPOUNDS

### 5.1 Hydrides

Zirconium and hafnium react with hydrogen at temperatures above  $700^\circ\text{C}$ , yielding an  $\alpha$ -phase and hydrides with a limiting M:H ratio of 1:2 (*see Hydrides: Solid State Transition Metal Complexes*). Under hydrogen pressure, absorption

**Table 2** Coordination numbers and polyhedra of zirconium and hafnium

| Oxidation state | Coordination number | Coordination polyhedron | Examples of compounds                                                                                                                                                   |

takes place with the formation of MH<sub>x</sub> hydrides by a transformation of the hcp lattice first to distorted cubic ( $x < 1.53$ ), then to face-centered cubic ( $1.53 < x < 1.70$ ), face-centered tetragonal ( $1.70 < x < 1.980$ ), and finally to a body-centered tetragonal lattice for MH<sub>2</sub>. During hydrogenation the density of the metal decreases to 5.5 (Zr) and 11.4 (Hf) g cm<sup>-3</sup> for the dihydride. This is accompanied by cracking of the solid, and this reaction can therefore be used as a method for converting the bulk metals to fine powders. Both hydrides are stable to air and can replace the metals as convenient starting materials for obtaining other binary compounds, and in the manufacture of ceramics and of foam aluminum using zirconium hydride.<sup>8</sup>

## 5.2 Borides

Both elements form borides of composition MB and MB<sub>2</sub>, but only zirconium yields a dodecaboride, ZrB<sub>12</sub>. The structure of the MB phase contains zigzag chains of boron atoms, and planar hexagonal nets of boron atoms exist in the structure of the MB<sub>2</sub> phase. In contrast, the ZrB<sub>12</sub> phase has an fcc NaCl-type structure (see **Borides: Solid-state Chemistry**).

## 5.3 Carbides and Silicides

Both metals and their dioxides react with carbon at high temperatures, yielding carbides, ZrC and HfC, with a NaCl

structure type. Their enthalpies of formation are 200.6 and 217.4 kJ mol<sup>-1</sup>, respectively. Very high melting points (3735 and 3890 °C) are characteristic of these compounds and the alloy of composition HfC·4TaC is the highest melting substance known (mp 3990 °C) (see **Carbides: Transition Metal Solid-state Chemistry**). The conductivities of these are as high as those of metals. They resist mineral acids up to 230 °C (100 °C in HNO<sub>3</sub>), but they react with halogens, oxygen, and nitrogen when heated.

There are several examples of M–Si systems. Silicides of composition M<sub>2</sub>Si, MSi, and MSi<sub>2</sub> are known for both metals. Zirconium also forms the Zr<sub>3</sub>Si<sub>2</sub> phase and hafnium the Hf<sub>5</sub>Si<sub>3</sub> phase (see **Silicon: Inorganic Chemistry**). All the silicides are insoluble in all mineral acids (except HF), and, unlike TiSi<sub>2</sub>, in 10% aqueous KOH.

## 5.4 Pnictides

Yellow nitrides MN are produced by direct interaction of the elements. It is interesting that the rate of reaction of zirconium with nitrogen is higher than that with oxygen, so the burning of the metal in air yields a mixture of nitride, oxide, and oxonitride, Zr<sub>2</sub>ON<sub>2</sub>. The reaction of MN with carbon is reversible. The nitrides also have a bcc structure, forming an uninterrupted series of solid solutions with the MC carbides. Their melting points are 2950 °C (Zr) and 2980 °C (Hf), and hafnium nitride is the most fire-resistant of all the metal nitrides (see **Nitrides: Transition Metal Solid-state Chemistry**). A

brown intermediate zirconium nitride of composition  $\text{Zr}_3\text{N}_4$  is produced by heating  $\text{ZrCl}_4$  at  $700^\circ\text{C}$  in a flow of ammonia (equation 3). Decomposition of the adduct  $\text{ZrCl}_4(\text{NH}_3)_2$  also yields  $\text{Zr}_3\text{N}_4$  via a nitridochloride ( $\text{ZrClN}$ ) stage.<sup>9</sup> Further heating of  $\text{Zr}_3\text{N}_4$  gives blue  $\text{ZrN}_x$  ( $x = 0.86\text{--}0.94$ ) above  $750^\circ\text{C}$  and  $\text{ZrN}$  above  $1000^\circ\text{C}$ . Treatment of  $\text{ZrI}_4$  with ammonia at  $500^\circ\text{C}$  gives a yellow  $\text{ZrIN}$  phase, whose structure is made up of  $\text{Zr--N}$  and  $\text{Zr--I}$  chains. These phases exhibit a 'metallic' conductivity that is higher than that of the pure metals, and  $\text{ZrN}$  is a superconductor below  $8.9\text{ K}$ .

Zirconium and hafnium nitrides dissolve in cold  $6\text{ M HF}$  but are stable in other acids except when heated (equation 4).

With phosphorus, zirconium and hafnium form phosphides of composition  $\text{M}_3\text{P}$ ,  $\text{MP}$ , and  $\text{MP}_2$ , which dissolve only in  $\text{HF/HNO}_3$  mixtures (see **Phosphides: Solid-state Chemistry**).  $\text{ZrP}_2$  can be also obtained by reaction of  $\text{ZrCl}_4$  with phosphine.

Arsenides of composition  $\text{MA}$ s and  $\text{MAS}_2$  are also known (see **Arsenic: Inorganic Chemistry**).<sup>10</sup>

## 5.5 Chalcogenides

Zirconium and hafnium react with *Chalcogens* on heating to give compounds of composition  $\text{ME}_2$ ,  $\text{ME}_3$ , and  $\text{ME}_5$ . Their thermal stability decreases in the order  $\text{E} = \text{S} > \text{Se} > \text{Te}$ . Oxochalcogenides,  $\text{MOE}$ , are formed on treatment of the metal dioxides with  $\text{H}_2\text{S}$ . The  $\text{MS}_2$  sulfides dissolve in hot hydrochloric acid, but the  $\text{MS}_3$  compounds do not react.  $\text{ZrTe}_2$  has a metallic conductivity, but  $\text{ZrS}_2$ ,  $\text{ZrSe}_2$ , and  $\text{HfTe}_2$  are semiconductors (see **Semiconductors**), and  $\text{HfS}_2$  is an insulator (see **Sulfur: Inorganic Chemistry**). The chalcogenides  $(\text{Cu,Cr})\text{ME}_4$  with spinel structures are semiconductors. Phases of the compositions  $\text{Ba}_5\text{Hf}_4\text{S}_{13}$  and  $\text{Ba}_6\text{Hf}_5\text{S}_{16}$  with perovskite blocks are considered as probable prospective materials for superconductors.<sup>11</sup> In the phase  $\text{K}_4\text{M}_3\text{Te}_{17}$ , the metal atom has a bicapped trigonal prismatic arrangement, as in  $\text{HfTe}_5$ .<sup>12</sup>

## 5.6 Oxides and Hydroxides

### 5.6.1 Oxides

Besides the dioxide  $\text{MO}_2$ , suboxides of zirconium and hafnium of composition  $\text{M}_6\text{O}$ ,  $\text{M}_3\text{O}$ , and metastable  $\text{MO}$  are known (see **Oxides: Solid-state Chemistry**). The dioxides are high melting ( $\text{mp ZrO}_2 = 2850^\circ\text{C}$ ,  $\text{HfO}_2 = 2900^\circ\text{C}$ ),

nonvolatile solids and find uses in the manufacture of fireproof or chemical resistant products. Besides the monoclinic crystal modification stable at room temperature, there are also two high-temperature modifications, tetragonal and cubic. In the presence of a little  $\text{CaO}$  a stable fluorite structure is formed, which avoids the injurious mechanistic consequences of the phase changes on repeated heating and cooling. Zirconia and hafnia possess an ionic conductivity via  $\text{O}^{2-}$  ions, in particular as solid solutions with other oxides, such as  $\text{Y}_2\text{O}_3$  (see **Ionic Conductors**). Zirconium and hafnium dioxides can be obtained both in the direct interaction of metals with oxygen and in the reaction of the tetrachlorides with water at  $250^\circ\text{C}$ , followed by heating in air at  $500^\circ\text{C}$ , or in oxygen at  $350^\circ\text{C}$  on a fluidized bed. Amorphous dioxides suitable for the manufacture of ceramics are produced by the hydrolysis of  $\text{Zr}$  and  $\text{Hf}$  alkoxides (see below). At elevated temperatures zirconia and hafnia can be reduced by  $\text{Ca}$  to the metals and by carbon to the carbides. Anhydrous zirconia is used as a support for metal and oxide catalysts (see **Oxide Catalysts in Solid-state Chemistry**).

### 5.6.2 Hydroxides

Zirconium hydroxide is precipitated by bases at lower pH than the hafnium compound.  $\text{Zr}$  and  $\text{Hf}$  are obviously unable to form true hydroxides, and these compounds are more correctly formulated as  $\text{MO}_2 \cdot x\text{H}_2\text{O}$ . Amorphous hydrous zirconia and hafnia ( $\alpha$ -phase) transform to microcrystalline forms ( $\beta$ -phase) with noticeable heat evolution. They lose water up to the composition  $\text{MO}_2 \cdot \text{H}_2\text{O}$  at  $140^\circ\text{C}$  ( $\text{Zr}$ ) or  $155^\circ\text{C}$  ( $\text{Hf}$ ). Hydrous zirconia has excellent absorptive capacity, particularly for oxygen-containing anions. For example, the concentration of  $\text{SO}_4^{2-}$  anions over hydrous zirconia is so low that no precipitate forms on the addition of barium salts to the filtrate. While the hydroxides of composition  $\text{M}(\text{OH})_4$  are not stable, in alkaline solutions,  $\text{M}(\text{OH})_5^-$  are present and even  $\text{M}(\text{OH})_6^{2-}$  anions have been reported in very concentrated alkalis. Salts of these anions, such as  $\text{Na}_2\text{Hf}(\text{OH})_6$ , can be isolated.

### 5.6.3 Zirconates and Hafnates

$\text{Zr}$  and  $\text{Hf}$  hydroxides are rather amphoteric (see **Amphoterism**). The metazirconates and -hafnates,  $\text{Q}_2\text{MO}_3$ , (where  $\text{Q}$  is a cationic counterion) and the corresponding poly compounds,  $\text{Q}_2\text{M}_2\text{O}_7$ ,  $\text{Q}_2\text{M}_3\text{O}_9$ , and  $\text{Ln}_2\text{M}_7\text{O}_{17}$  ( $\text{Ln} = \text{La}$ ,  $\text{Nd}$ ), are known. A common route for their preparation is the firing of zirconia and hafnia with the appropriate metal carbonate or nitrate. In  $\text{K}_2\text{ZrO}_3$ , zirconium has a tetragonal pyramidal arrangement. Zirconates and hafnates of  $\text{M}^{\text{II}}$  cations of composition  $\text{M}^{\text{II}}\text{ZrO}_3$  usually possess a perovskite structure, whereas  $\text{M}_2^{\text{II}}\text{ZrO}_4$  compounds often have a spinel structure. Lead zirconate,  $\text{PbZrO}_3$ , is a segnetoelectric material, like  $\text{PbTiO}_3$ .

#### 5.6.4 Heteropolyacids

Zirconium forms heteropolyacids with molybdenum, such as  $\text{H}_8[\text{Zr}(\text{Mo}_2\text{O}_7)_6]$ , whose alkali metal derivatives have been isolated. In the first member of the series, of composition  $\text{ZrMo}_2\text{O}_7(\text{OH})_2(\text{H}_2\text{O})_2$ , the zirconium atom has a pentagonal bipyramidal arrangement (see *Polyoxometalates*).

#### 5.6.5 Peroxo Compounds

Zirconium and hafnium tetrahalides react with hydrogen peroxide in alkali solution to yield  $\text{M}(\text{OH})_3\text{OOH}$ . The maximum content of peroxo units per metal atom has been observed in  $\text{K}_4\text{Zr}(\text{O}_2)_4 \cdot 6\text{H}_2\text{O}$ , which is a derivative of the unknown orthoperzirconic acid  $\text{Zr}(\text{OOH})_4$ .

### 5.7 Halides and Oxohalides

Zirconium and hafnium form halides of composition  $\text{MX}_4$  and also  $\text{MX}_3$ ,  $\text{MX}_2$ , and  $\text{MCl}$  (see below) (see *Fluorides: Solid-state Chemistry* and *Halides: Solid-state Chemistry*). All the tetrahalides are colorless (except for the red-brown  $\text{HfI}_4$ ) and volatile solids, melting only under pressure. The tetrachlorides are produced by chlorination of the dioxides in the presence of coke. The tetraiodides are formed in a direct reaction of iodine with the metal, but the use of the hydrides is more convenient. The halides of hafnium are more stable to heat than those of zirconium. Decomposition of tetraiodides to yield pure metals is used in the van Arkel–de Boer process. The tetrahalides (except for the fluorides) readily dissolve in water, with formation of the oxohalides  $\text{MOX}_2$ . The reaction of  $\text{MF}_4$  with water yields  $\text{MF}_4 \cdot 3\text{H}_2\text{O}$ , which is stable to hydrolysis.  $\text{ZrF}_4 \cdot 3\text{H}_2\text{O}$  contains dimers,  $(\text{H}_2\text{O})_3\text{F}_3\text{Zr}(\mu\text{-F})_2\text{ZrF}_3(\text{H}_2\text{O})$ , while the hafnium complex is a polymer with double  $\text{Hf-F-Hf}$  bridges (see *Bridging Ligand*).<sup>13</sup> The tetrahalides have a monomeric, tetrahedral structure in the gas phase (except for  $\text{HfF}_4$ , which forms a dimer). In the solid state, the tetrafluorides have a structure with an antiprism of eight fluorides around each metal atom, while tetrachlorides are composed of chains of edge-sharing distorted octahedra of six chlorides.

Depending on the temperature, heating  $\text{HfF}_4 \cdot 3\text{H}_2\text{O}$  in air gives oxofluorides that are mostly isomorphous with the corresponding zirconium compounds:  $\text{Hf}_4\text{OF}_{14}$ ,  $\text{HfOF}_2$  or  $\text{Hf}_2\text{OF}_6$  (no zirconium analog),  $\text{Hf}_3\text{O}_2\text{F}_8$ , and  $\text{HfO}_2$ . The differences between Zr and Hf are also evident in the diverse composition of the products of hydrolysis and thermal decomposition of  $\text{MF}_4 \cdot 3\text{H}_2\text{O}$ :  $\text{Zr}_4\text{F}_{10}(\text{OH})_6 \cdot 3\text{H}_2\text{O}$  and  $\text{Hf}_4\text{F}_{12}(\text{OH})_4 \cdot 4\text{H}_2\text{O}$ ,  $\text{Zr}_4\text{F}_{10}\text{O}_3$  and  $\text{Hf}_4\text{F}_{12}\text{O}_2$ . Anhydrous hygroscopic oxochlorides of zirconium and hafnium  $\text{MOCl}_2$  were obtained according to equation (5). On heating they disproportionate (equation 6). The hydrated oxochlorides  $\text{MOCl}_2 \cdot 8\text{H}_2\text{O}$  decompose above  $65^\circ\text{C}$ , yielding the dioxides.

## 6 SALTS OF OXOACIDS

### 6.1 Silicates

Silicates of zirconium,  $\text{ZrSiO}_4$  (zircon), and hafnium,  $\text{HfSiO}_4$ , are the only crystalline phases in the  $\text{MO}_2\text{-SiO}_2$  system. Their fusion with molten  $\text{Na}_2\text{SiO}_3$  yields double silicates,  $\text{Na}_2\text{MSiO}_5$  and  $\text{Na}_4\text{MSi}_2\text{O}_8$ .

### 6.2 Nitrates

Anhydrous volatile nitrates  $\text{M}(\text{NO}_3)_4$  are obtained by the interaction of the chlorides with  $\text{N}_2\text{O}_5$  (equation 7):

They have monomeric structures with bidentate  $\text{NO}_3$  groups.  $\text{M}(\text{NO}_3)_4$  and  $\text{MO}(\text{NO}_3)_2$  react with water more slowly than do the titanium analogs, yielding hydrates of composition  $\text{M}(\text{NO}_3)_4 \cdot 5\text{H}_2\text{O}$  and  $\text{MO}(\text{NO}_3)_2 \cdot n\text{H}_2\text{O}$  ( $n = 2, 6$ ); both can be isolated from cold concentrated nitric acid. As in the case of other  $\text{MOX}_2 \cdot n\text{H}_2\text{O}$  salts, there are no ‘zirconyl’ or ‘hafnyl’ units ( $\text{MO}^{2+}$ ) in the structures of these compounds. The absorbance bands around  $850\text{--}900\text{ cm}^{-1}$  in the IR spectra of these compounds, which were earlier considered evidence for the presence of zirconyl or hafnyl  $\text{M=O}$  bonds, are now assigned to bridging  $\text{M-O-M}$  linkages. The eight-coordinate metal atom in  $\text{MO}(\text{NO}_3)_2 \cdot 2\text{H}_2\text{O}$  is surrounded by two hydroxyl groups, four water molecules, and two monodentate  $\text{NO}_3$  groups; in anhydrous  $\text{ZrO}(\text{NO}_3)_2$ , on the other hand, oxygen bridged chains are present. ‘Dizirconyl’,  $\text{Zr}_2\text{O}_3(\text{NO}_3)_2 \cdot 5\text{H}_2\text{O}$ , and ‘dihafnyl’,  $\text{Hf}_2\text{O}_3\text{Cl}_2 \cdot 5\text{H}_2\text{O}$ , salts have no terminal  $\text{M=O}$  bonds either. Hafnium nitrate forms a volatile adduct  $\text{Hf}(\text{NO}_3)_4 \cdot \text{N}_2\text{O}_5$ ; zirconium nitrate, however, does not. Mixed nitrates,  $\text{Q}[\text{M}(\text{NO}_3)_6]$ , are known, where  $\text{Q} = \text{NR}_4^+$ .

### 6.3 Phosphates

The orthophosphates  $\text{M}(\text{HPO}_4)_2$  are practically insoluble in mineral acids (except HF) and can be precipitated from strong acid solutions as hydrates with one or two water molecules. This is a method for separating Zr and Hf from other metals (except Pa). The Hf salts are less soluble than those of Zr and accumulate in the precipitate from sulfuric acid solution. Both  $\text{Zr}(\text{HPO}_4)_2 \cdot n\text{H}_2\text{O}$  phases have a layered structure and can be intercalated by quite large molecules, such as phen or aminoferrocene.<sup>14</sup> The pillared materials so obtained have pore dimensions approaching those found in

zeolite Y and can be used as sorbents or catalysts. Heating the orthophosphates transforms them to pyrophosphates,  $M(P_2O_7)$ . Mixed phosphatosilicates of zirconium and sodium, such as  $Na_3Zr_2Si_2PO_{12}$ , are Na superionic conductors (*see Phosphates: Solid-state Chemistry*).

#### 6.4 Sulfates
